This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

New York.

PREFACE.

The undersigned publishers of the authorized American Reprint of the London Chemical News, in submitting to the public their first semi-annual volume, desire to acknowledge the favor with which their undertaking has been received, and to call renewed attention to its features of interest and value.

From the outset they were assured that by its republication, the cause of science in the United States, and the best use of its application to the arts and manufactures of life, together with Pharmacy and Medicine, were to be largely promoted. The welcome which our endeavor to extend real scientific information has met with, and the support it has gained, together with the intrinsic worth and wide reach of the matter contained in these pages, are our guarantee for that result.

The Chemical News is not a journal of recent origin. In connection with its predecessor, The Chemical Gazette, it has, for more than twenty-five years, fully and faithfully represented the progress of Chemistry and cognate sciences in England and throughout the world. Its present position has been attained by successive improvements, until it now numbers among its contributors nearly every chemist of note in Europe and America. In its columns some of the most important chemical and physical discoveries have for the first time been made known, and investigators frequently make use of its pages to secure priority of a discovery, by the bare mention of facts and results, before publishing their full papers. The good influence of this journal, in the progress of pure chemical research and advancement, has been felt for years. It is now everywhere cited as the great repository of chemical knowledge, discussion, and authority. Its editorial staff is made up of gentlemen in the first rank of science. Moreover, as the Chemical News is not the organ of any institution, clique, professional or trading firm, its conductors are under no liability to act or write, at any time, in other than a fearless and independent manner. No trade puffs are ever inserted here—no unworthy books or patents are ever commended. Its character in these and kindred respects is one of honest pride with its proprietor and publishers.

But however high the position of this journal as a treasury of all that is fresh and valuable in chemistry, it would be a mistake to consider the Chemical News as covering that department of science alone. It is hardly less a periodical of importance to the medical profession, for it often contains papers giving the methods and results of the thorough application of chemistry to medicine. These are of such a nature as to present the fruits of studious observation and thought in a manner elsewhere unattained. Several papers in the current volume may stand in support of this, as also to show the attention given by its editors to public sanitary questions.

The Chemical News, again, is a rich medium of information to every theoretical and practical pharmaceutist, druggist, and apothecary. In its reports of the British Pharmaceutical Society, and the British Pharmaceutical Conference, with occasional papers upon special topics, and its chemical notices from foreign sources, it constantly supplies matter indispensable to every well-trained and furnished member of this respected and important calling. It affords much gratification to the American publishers to be the means of advancing the character and qualifications of so numerous and wide-spread a class in the community.

Numbers of extensive manufacturers in this country, of many sorts, have for years past prized the Chemical News as a valued auxiliary and guide in the various processes by which their goods and fabrics have been prepared for consumption and use, and the number of such persons is on the increase.

Photography and the finer arts are the objects of watchful and conscientious notice at the hands of those who prepare the Chemical News. New processes and profitable suggestions in this connection are not seldom brought out for the first time in its pages.

In its analyses of metals, its record of the developments in mining throughout the world, its attention to mineralogy, its discussions of mechanics and electricity, it is believed to be without a competing rival.

To fill so wide a range of application is apparently difficult of accomplishment. That it is done, and in the most thorough way, no regular reader of the Chemical News need be informed.

The general features of this journal may be thus summed up in detail:

1. Leading and Editorial articles by the well-known Editor, Mr. William Crookes, F.R.S., on all topics within the proper scope of the journal. Besides these, each number contains leading articles of the same nature, by other persons eminent in the walks of science. In the space devoted weekly to "Communications Received," subscribers will recognize the shining positions held by its corespondents. When an article appears without a full signature, it is by no means to be supposed that it is necessarily the production of the responsible Editor: anonymous contributions from the most distinguished chemists of the day often grace the columns of the Chemical News.

2. Graphic pictures of Foreign Science by the Paris correspondent of the Chemical News, one of the first scientific men in France, and an expert in lucid scientific exposition, the Abbé Moigno. The interest and the availability of these letters cannot well be overstated. From a practical point of view, they add very largely to the value of the Magazine for a wide circle of students and readers.

3. Its Reports of Societies have ever been a marked feature of the Chemical News. From the first number, its readers have always had presented to them a complete account of the proceedings of the Chemical,

Royal, and Pharmaceutical Societies, and the Royal Institution. These matters are given either verbatim or in a form more or less condensed, according to the importance of the subject, the reports being in many cases prepared by the speakers themselves. The enterprise of this journal in its late admirable report of the Dundee meeting of the British Association for the Advancement of Science, printed in this volume, is but a specimen of the readiness of its conductors always to procure the best accounts of the best gatherings. The Manchester Literary and Philosophical Society, the British Medical Association, the French Academy of Sciences, the Royal Dublin Society and Quekett Microscopical Club, are among those whose transactions appear in the present volume. The Abbé Moigno is the reporter of the French Academy, and each weekly impression of the Chemical News usually presents a record of that Society's meetings from his masterly hand.

4. Fresh, prompt, and impartial notices of scientific books.

5. Columns for correspondence which are freely used, and possess a lasting as well as ephemeral value. Here each new theory, and every great step in the changing phases of notation or nomenclature which have occupied the attention of the chemical world, are, during their tentative state, the subjects of discussion. Practical recipes on matters of general and particular interest, communications concerning traffic in scientific materials, have all found, and will hereafter find, in this department, a fitting and serviceable receptacle.

6. Chemical Notices from Foreign Sources, giving a condensed account of every important chemical paper in the world, as soon as it is published. To give a regular and detailed account of such papers would fill an octavo volume weekly. In this department considerable judgment is required to decide what papers to omit altogether, and which to curtail, so as to allot to each subject its due prominence. This responsible office of selection and condensation is entrusted to a chemist thoroughly competent to carry out this design.

7. Miscellaneous paragraphs of general concern to those interested in the relations of science to all matters affecting individual and social well-being and comfort.

8. Contemporary Scientific Press. This is a new feature, recently introduced, at the suggestion and request of many leading chemists. It purports to give, as soon as possible after publication, the title of every chemical paper in the world: to compile it, every accessible scientific periodical is ransacked.

9. Lists of English Patents.

10. Notes and Queries—for the interchange of brief question and reply on a wide range of chemical, scientific, and general topics.

11. Brief Answers to Correspondents, Lists of Communications, Books Received, etc., etc.

Besides the features thus enumerated, every phase of affairs in the scientific world, with all important events, receive such regard and place in the pages of the Chemical News as they merit. For illustration, it is proper to remark upon the elaborate obituary notice of the lamented Faraday, which appears upon page 268 of this volume, as also upon the introductory address at St. Bartholomew's Hospital Medical School, by Dr. Odling, F.R.S., printed on page 306. The character and value of a journal that furnishes to its readers such a series of lectures as those delivered at the Royal Institution of Great Britain, by Dr. William Allen Miller, LL.D., on "Spectrum Analysis, with its application to Astronomy," published on pp. 29, 67, 135, 186, admit of no question.

The long period of existence of the Chemical News, and the high position which it has always taken, have gradually led to its introduction into all the public and private laboratories, the museums, institutions, and libraries in England, on the Continent, and in America. Its original and editorial articles are constantly reprinted in the Old and New World, and have been translated into German, French, Italian, Spanish, Russian, and other languages. The admission of an original paper, therefore, into its pages, secures its rapid diffusion over the whole world. With the exception of the *Philosophical Magazine*, established in 1798, and the *Proceedings of the Learned Societies*, no other English scientific journal enjoys this universal publicity.

Stimulated by their knowledge of all that has been said, the undersigned, in reprinting the Chemical News in America, with the authorization of Mr. Crookes, its distinguished editor, who regularly furnishes them with early weekly sheets of the English issue, and who will, after January 1, 1868, withdraw the circulation of the English edition in the United States, have spared no pains to make its appearance correspond to its place and character in the world of science. The American edition, printed in monthly instead of weekly numbers, has some practical advantages for its subscribers by virtue of this fact. Arrangements are made to secure and retain the best and most careful editorial ability to provide for the labor which such a change necessitates, and to superintend the reissue in its passage through the American press. The numbers of the reprint may henceforth be expected to be as close a *fac-simile* of the English edition as the case will admit of. The mechanical execution of the American edition of the Chemical News will not, we are confident, suffer any disparagement by comparison with its original.

In consequence of the increased cost of manufacture and the liberal annuity paid to the English Proprietor, the undersigned are constrained to fix the subscription price of the Reprint at $3.00 *per annum*, in advance, postage free, on and after January 1, 1868.

With this introduction, Volume I. of the American Reprint of the Chemical News is offered to the public by

THE AMERICAN PUBLISHERS.

December, 1867.

INDEX.

THE CHEMICAL NEWS

AND

JOURNAL OF PHYSICAL SCIENCE.

Volume 1. July, 1867.

ENGLISH DISCOVERERS AND FRENCH ACADEMICIANS.

A COMMUNICATION on the estimation of copper, from M. de la Follye, was recently brought before the French Academy by M. Pelouze. The author says that, in attempting to estimate copper by Pelouze's process (precipitation by a standard solution of sulphide of sodium), he met with certain difficulties which led him to try another process, and he ultimately decided upon adding a standard solution of cyanide of potassium to an ammoniacal solution of the copper which was to be determined. M. de la Follye calls this "only a modification of the excellent method of that eminent chemist," Pelouze; and as that eminent chemist himself presented the paper, we may assume that he admitted the substantial accuracy of the statement.

We are so accustomed to see English discoveries rediscovered by French chemists and brought before the Academy of Sciences as undoubted novelties, that in general we refrain from drawing attention to this unfairness. It appears to be one of the stages through which an English discovery must pass before it obtains Continental recognition; but for several reasons we cannot allow this instance to pass over without animadversion. Every chemist will at once perceive that the new process of M. de la Follye is absolutely identical with that of Henry Parkes, published in the *Mining Journal* in 1851. Owing to its neatness, convenience, and general accuracy, it has become almost universally employed in the commercial analysis of copper ores, and we venture to say that there is scarcely a laboratory in Europe in which Parkes's process has not been more or less used. In all standard works on analysis, English and German, Parkes's process stands side by side with Pelouze's process; and were it not that an English writer, generally remarkable for his literary accuracy, has appeared to acquiesce in M. de la Follye's pretensions, we should say that it was utterly inconceivable how any chemist could venture to publish so old and well-known a process as original.

We are glad to see that this discreditable attempt at appropriating Henry Parkes's well-earned laurels has met with an indignant protest from E. F. Dürre, of Berlin, in the *Berg. und Hüttenmännische Zeitung* for March 22. He says that there is "nothing rare in their Western neighbours ignoring foreign merit altogether; but in such a case as this, when a well-known process is brought, as a new discovery, before an important learned Society, by a man of wide-spread reputation and acknowledged ability, it becomes the duty of every one not to content himself with the mere rectification of the error, but to enter a loud protest against such a claim."

After pointing out the utter groundlessness of MM. de la Follye's and Pelouze's pretensions, Herr Dürre concludes by saying that it is necessary that this circumstance be rightly appreciated, to show how cautious one must be in respect to a French communication, even when it is brought before the Academy of Sciences by one of its members.

THE USE AND ABUSE OF BLACKBALLING.

WE feel constrained again to draw attention to certain unprecedented proceedings which have distinguished the last two meetings of the Chemical Society. For some years the laxity of Fellows in exercising their right of blackballing candidates for Fellowship whose claims were clearly inadequate to entitle them to that honour has been a subject of general comment. Owing to the exceptional position held by the editor of this paper as journalist, and at the same time as a Fellow of the Chemical and other learned bodies, a friendly correspondence with many chemists in all parts of the country has been carried on at one time or another on matters connected with their Society. We are thus necessarily in a favourable position for ascertaining the existence of any grievance among the members.

The Council, as announced by the President at the anniversary meeting, finding that a wide-spread feeling of dissatisfaction existed at the undue facility with which anybody could join the Society, and that this privilege had been on more than one occasion seriously perverted for trade purposes, have lately had under discussion the best method of diminishing this abuse, and restoring to the title F.C.S. its former honourable distinction.

The subject of raising the qualification or restricting the admissions is beset with many difficulties; but those of our readers who are Fellows of the Chemical Society may rest assured that this question is receiving, and will continue to receive, the very serious attention of the Council. When the time comes for a proposal to alter the by-laws at a general meeting, we are convinced that the explanations and the reasons for such alterations, which will then be brought forward, will be adopted by a large majority.

The fact, then, is, that candidates have been admitted too freely. Country members complain that their brother members in London never exercise the right to blackball a candidate. It seems strange that attention should now have to be called to the fact that this undoubted right, so long in abeyance, is now apparently abused in a manner so reckless and suicidal as to seriously imperil the interests of the Society.

A few weeks ago we alluded to the abortive attempt on the part of a few junior members to rearrange the list of Council and officers. Failing signally in that endeavour, it would seem as if they were now attemptings, by a concerted plan of action, to assume the governing power in the Society by blackballing candidates irrespective of scientific position or attainments. Thus, party interests are made secondary to scientific progress, and the healthy existence of the Society is imperilled for the gratification of private pique.

Of the five hundred Fellows of which the Society consists, seldom more than forty regularly attend the meeting, and of these the majority have hitherto abstained from balloting. According to the by-laws, "when less than three-fourths of the Fellows who vote are in favour of the candidate, he shall not be elected a Fellow;" supposing then that forty-seven voters are present, it will be seen that a dozen disaffected members are able practically to control the ballot-box. Fellows should remember that the possession of a legal right to blackball a candidate, does not imply a moral right to abuse this privilege. They hold this in trust, to be exercised honestly for the good of the Society. In the "obligation" which each Fellow signs on his admission, he engages to "promote the interests and welfare of the Chemical Society," and he is not justified in recording an adverse vote simply to gratify the pitiful ambition of a small party, or to exercise a paltry spite against those who have won the confidence and support of the majority of members.

Between those elected and those rejected at the last meeting we wish to make no invidious comparisons. Few will dispute the qualifications of the fortunate candidates; but those rejected, from their position and scientific acquirements, may be fairly said to possess a very good claim to the coveted honour. In the absence of definite acquaintance with the qualifications of any candidate, the Fellows are, in a certain sense, morally obliged to vote for any one who has so excellent an array of recommenders from personal knowledge as could be seen on the certificates of the gentlemen who had to suffer, for no fault of their own, the indignity of rejection.

Before it is too late, we wish to appeal to the good sense of those who think themselves aggrieved. If they conscientiously object to a candidate, no one would ask them to violate their convictions by voting in his favour; but if they have any grievance, or wish to propose any alteration in the method of conducting business, let them adopt a straightforward course. We can promise them a patient and attentive consideration of any measure they may wish to introduce; but it is unbearable that ten or a dozen young men should, by devious strategy, attempt to overrule the wishes of the Council and of the great body of members.

Apart from the bad policy of making themselves personally obnoxious to the leading men of their science, the malcontents should consider that they are powerless permanently to control the elections; they could but snatch a momentary triumph, for immediately after the necessary alteration of the by-laws the rejected candidates, if they still cared for the honour, would come forward with a fair prospect of election. A slight modification in the by-laws for the election of Fellows, which would certainly be approved at a general meeting if brought forward by the Council, would take from any clique a power which may be so unwisely wielded. The problem to be solved is how to guard against the admission of unfit persons into the Society, and at the same time to prevent voting by ballot becoming an organ for the gratification of private pique. In several ways the necessary alteration could be made, but we hope such a step will not be forced upon the Council.

ELECTION OF FELLOWS AT THE CHEMICAL SOCIETY.

It was suggested last week that it would probably be necessary to alter some of the By-laws regulating the admission of Fellows into the Chemical Society, and we stated that the problem to be solved was how to guard against the admission of unfit persons, and at the same time to prevent the ballot becoming an organ for the gratification of personal pique. On looking more carefully into the Charter and By-laws of the Chemical Society, it appears that there is to be found a very simple solution of the latter part of this problem. Attention being drawn to the subject, it has not failed to strike most persons as manifestly unjust that the decision on an important question, brought before a meeting of the members, should be determined according to the wishes of the minority; and it shows how harmoniously the

Society and its officers have hitherto worked together that this hardship has never been felt before. On his admission, each Fellow received the regulations of the Society, together with sundry other formal documents; but we venture to say that not many looked at them a second time, and few will now be able to lay hands on a copy of the charter and by-laws, to which we now propose to direct attention. When everything is going on smoothly, the laws and regulations of the Society are dormant.

It now appears that for many years the Society has been acting contrary to the charter, in electing Fellows, honorary and foreign members, and associates, according to the existing by-laws.

By the third paragraph of the Charter of Incorporation, granted to the Society in 1848, it is declared—

> "That at all General Meetings and meetings of the Council the majority present and having a right to vote thereat respectively shall decide upon the matters propounded at such meetings."

Again, the concluding paragraph of the Charter declares,

> "That no resolution or by-law shall, on any account or pretence whatsoever, be made by the said body politic and corporate in opposition to the general scope, true intent and meaning of this our charter; and that if any such rule or by-law shall be made, the same shall be absolutely null and void to all intents, effects, constructions, and purposes whatsoever."

Now, it is very evident that the by-law, making the election of a candidate depend upon the votes of three-fourths of the Fellows present, is in direct contravention to the "true intent and meaning" of the first-quoted paragraph of the charter; and therefore such by-law is, according to the terms of the second citation from the charter, "absolutely null and void to all intents, effects, constructions, and purposes whatsoever."

But it may be argued that the third paragraph of the charter refers only to anniversary meetings or extraordinary meetings of the Society. An attentive examination will, however, show that by the term "general" meeting is intended that which is now commonly called an "ordinary" meeting. The term "*ordinary* meeting" strictly means *regular* or *customary* meeting; a *general* meeting means one public or common to the whole of the Fellows. Custom has sanctioned the omission of the word "general" as qualifying the ordinary meetings, but it is still retained in by-law, which speaks of an *extra*-ordinary general meeting, which, logically and grammatically, can only mean a *general meeting* held *extra*, or in addition, to the *ordinary* bi-monthly meetings.

The term "general meeting" occurs several times in the charter, but nowhere do we find the terms "ordinary" and "anniversary" meetings. When, however, we refer to the regulations of other learned societies, no longer can there be any doubt as to the meaning of the term "general" meeting. In the Charter of the Royal Society no mention is made of meetings of the members, ordinary, extraordinary, or general. But in the Charter of the Zoological Society the term "general" meeting is used in a sense applicable only to ordinary meetings; and in the by-laws the monthly meetings of the Society are invariably spoken of as "general meetings," or "ordinary general meetings." In the charters of the Linnæan and Geological Societies likewise the term "general meeting" is used to express the ordinary meetings of the members, and in the by-laws these are invariably termed "general" meetings; the 9th section of the rules of the latter society, in fact, state that "the *general* meetings to be held by the Society shall be of three kinds:—1. *Annual;* 2. *Special;* 3. *Ordinary.*" It cannot, therefore, be doubted that the term "general" meeting in the third paragraph of the Charter of the Chemical Society means the same as the term "ordinary" meeting does in the by-laws.

No one, we imagine, will dispute that the election of Fellows is a "matter propounded" at a meeting upon which the "majority present" are to decide. On the contrary, the question as to whether the candidate is to be admitted to the Fellowship of the Chemical Society is a very important matter propounded to those present who have a right to vote, and the question, above all others, which should be carried by a numerical majority.

In strict logical interpretation, therefore, those candidates who were blackballed at the recent meetings of the Society were excluded from the Fellowship in error. A numerical majority of voters were in favor of their admission, and at the present time the blackballees are as strictly entitled to the letters F.C.S. as are any of the blackballers.

We confess we see only one course to be pursued in respect to the by-laws which remit the decision on such important matters as the election or removal of Fellows to a small minority, in opposition to the wishes of the great bulk of those present. Strictly speaking, these restrictive by-laws never had any legal existence, and they should at once be replaced by others in conformity with the charter.

One-half of the problem now under discussion—that of preventing voting by ballot becoming an organ for the gratification of personal pique—has solved itself in a manner which leaves nothing to be desired. The first part of the question—How to guard against the admission of unfit persons into the Society—is one in which Council and Fellows are free to act, for the charter specially provides that they "may alter, vary, or revoke, and may make such new and other by-laws as they shall think most useful and expedient for the said body politic and corporate, so that the same be not repugnant to these presents." Thus the way is clear to a satisfactory settlement of the recent unwarrantable proceedings and the permanent prevention of their recurrence, and to the establishment of safeguards against the degradation of the Fellowship of the Chemical Society.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Determination of Soda in the Assay of Potashes, by M. Graeger.

Commercial potashes generally contain soda. To determine the proportion by volumetric assay, we must know the quantity of pure alkaline carbonates contained in the substance to be assayed. For this object the author dissolves 6·911 grammes of the potash to be assayed in 100 c.c. of water, weighs the insoluble portion, and determines in one part of the solution the quantity of chlorine (chloride of potassium), in another the quantity of sulphuric acid (sulphate of potash), determinations which may be made with standard solutions. The estimation of the alkalies is effected on 10 c.c. of the solution by means of normal nitric acid; and from the quantity of acid added the relation of soda to potash may be calculated, as the total quantity of alkaline carbonates is known by subtracting from the total weight of substance taken the weight of the insoluble matter of the chloride and sulphate of potash.

To assist in the employment of this method, the author has drawn up a table giving the amounts of carbonate of potash and carbonate of soda corresponding to the quantity of normal nitric acid necessary for their saturation:—

KO,CO_2. Grammes.		NaO,CO_2. Grammes.		NO_5. C.C.
1·00	+	0·00	require	14·47
0·95	+	0·05	'	14·69
0·90	+	0·10	"	14·92
0·85	+	0·15	"	15·14
0·80	+	0·20	"	15·35
0·75	+	0·25	"	15·57
0·70	+	0·30	"	15·79
0·65	+	0·35	"	16·01
0·60	+	0·40	"	16·23
0·55	+	0·45	"	16·45
0·50	+	0·50	"	16·67
0·45	+	0·55	"	16·89
0·40	+	0·60	"	17·11
0·35	+	0·65	"	17·33
0·30	+	0·70	"	17·55
0·25	+	0·75	"	17·76
0·20	+	0·80	"	17·97
0.15	+	0·85	"	18·19
0·10	+	0·90	"	18·40
0·05	+	0.95	"	18·62
0·00	+	1·00	"	18·84

If, for example, it is found that the crude potash taken contained 5·1134 grammes of pure alkaline carbonate, and it required 79 c.c. of normal nitric acid, the proportion 5·1134 : 1·0 : : 79 c.c. : x will give the quantity of normal acid ($x = 15·45$ c.c.) which one gramme would have required, and on reference to the above table it is found that 15·45 c.c. of normal acid correspond to 0·22 of carbonate of soda and 0·78 of carbonate of potash, or 78 per cent.—*Journal für praktische Chemie*, t. xcvii. p. 496 (1866), No. 8.

On the Preparation of Pure Chloride of Ammonium, by J. S. Stas.

I. Chloride of Ammonium from the Ammonia extracted from Sal Ammoniac, purified by Aqua Regia.—Ten litres of a boiling saturated solution of sal ammoniac were added to a litre of nitric acid of specific gravity of 1·4. The liquid was kept boiling as long as it gave off chlorine. The sal ammoniac which separated from the liquid on cooling was dissolved in pure boiling water, and the solution was boiled with a twentieth of its volume of nitric acid as long as chlorine was produced. The liquid, diluted with pure water until it no longer deposited chloride on cooling, was poured upon hydrate of calcium contained in a large retort to set free the ammonia. The latter, first washed in water, was then placed into pure water. The ammoniacal solution produced was in its turn nearly saturated by a current of pure hydrochloric acid.

The chloride of ammonium, which was deposited by the liquid after its concentration and cooling, was dried at 100° by passing continuously a current of ammoniacal gas into the long-necked globe in which it was being dried. This being done, I sublimed the sal ammoniac with the least possible elevation of temperature, keeping the neck of the globe as far as possible full of dry ammoniacal gas.

The chloride volatilised without leaving the least trace of carbon—a proof that the sal ammoniac contained no compound ammonia. However, it was easy to perceive that the bottom of the globe, which was of ordinary glass, was very slightly attacked. On breaking it to detach the sublimed chloride, I found, in fact, that traces of chlorides of sodium and calcium were formed at the expense of the substance of the glass, and that some silica was set free. By means of spectrum analysis I found that the sublimed sal ammoniac, which was quite colourless, and remarkably transparent, contained traces of sodium, but it was absolutely free from calcium.

In order to eliminate the traces of sodic chloride, which were carried over with the vapour of the sal ammoniac, I sublimed it two more times in an atmosphere of ammonia, at the lowest possible temperature, devoting to this operation some *hard glass* vessels that I had had made expressly for the transformation of the alkaline chlorides into nitrates of these metals. At the temperature at which the chloride of ammonium was sublimed these vessels resisted its vapour perfectly. In the notice "*On the Transformation of the Chlorides into Nitrates,*" I give the composition of the glass of these vessels.

The chloride of ammonium, before being employed in this determination, was heated in the same vessel in which it was weighed, up to the point of giving off vapour, so as to drive off the condensed ammonia.

II. Chloride of Ammonium produced by means of Ammonia prepared from the Commercial Sulphate.—To prepare chloride of ammonium by means of ammonia, from commercial sulphate, I first treated the latter compound as follows:—Two kilogrammes of sulphate were heated with a kilogramme and a half of concentrated sulphuric acid up to the temperature at which the sulphate begins to decompose with effervescence. I then introduced nitric acid by degrees into the mixture until the liquid, which was of a tolerably strong blackish-brown colour, had become quite colourless. The compound ammonias and organic matters contained in the sulphate are thus completely destroyed, with liberation of carbonic anhydride.

The acid sulphate, suitably cooled, was poured into about ten times its volume of cold water, and the excess of acid nearly saturated by lime water. When the sulphate of calcium was deposited, the supernatant liquid was mixed with a sufficient excess of slaked lime contained in a very large globe, and was heated in a bath of a saturated solution of common salt, so as to drive off the ammonia it contained. The latter, after washing in water, was put into pure water.

The ammonia, when dissolved, was saturated by a current of pure hydrochloric acid. The solution of sal ammoniac produced was evaporated to dryness in a globe of *hard glass*, and the residue was sublimed in an atmosphere of ammonia obtained from part of the same chloride.

The sal ammoniac volatilised without leaving a trace of a residue. The sublimed product was absolutely colourless; it gave off an ammoniacal smell. Before being employed it was heated until vapour was given off, so as to drive off the condensed ammonia.

III. Chloride of Ammonium obtained by means of the Ammonia produced by the Reduction of Nitrite of Potassium.—To procure nitrite of potassium, I had recourse to Stromeyer's process. I heated to redness one kilogramme of nitre with four kilogrammes of lead in a small cast-iron crucible. When the vivid incandescence which at first ensued was over, and the mixture sufficiently cooled, I washed it in boiling water. I then, by means of a solution of hydrosulphate of potassium, eliminated the lead from the solution of nitrate. After removing the sulphide of lead and concentrating the remaining solution, I added fifteen litres of a solution of caustic potash of a specific gravity of 1·250. This mixture was poured into a globe of a capacity of twenty-five litres, placed in a sand-bath, and which contained a mixture of three kilogrammes and a half of granulated zinc, deprived of its carbon by fusion with a mixture of carbonate of soda and nitre[*] and a kilogramme and a half of iron, which, after having been oxidised by calcination in contact with air, had been reduced by hydrogen.

The globe communicated through a large bent tube, with an arrangement for washing and condensing the ammonia to be produced. This arrangement consisted of—1st, a large tubulated retort placed upon a furnace and containing a certain quantity of pure water, into which the tube coming from the globe was plunged; 2nd, a large Woulff's flask with three tubes, containing half a litre of pure water; 3rd, a Woulff's flask containing water acidulated with hydrochloric acid, for the purpose of retaining the ammonia carried over by the current of hydrogen, which is produced very freely when the reduction of the nitrite takes place and the liquid in the globe is boiled.

Before distilling the liquid in the globe, I allowed the materials to react during seventy-two hours, so as to reduce as completely as possible the nitrite of potassium into ammonia and oxide of potassium and zinc. After this I boiled the liquid gently for two hours, keeping the water boiling in the retort and cooling that contained in the large Woulff's flask intended for the condensation of the ammonia.

It is indispensable to boil the liquid contained in the globe *very gently*, as it bubbles up violently by the disengagement of the hydrogen at a high temperature. I recommend chemists who wish to procure absolutely pure ammonia by this means to distil the liquid decanted from the mixture of zinc and iron. As I ascertained in a subsequent trial, after the reduction of the nitrite into ammonia has taken place, the decanted liquid may be distilled without the least difficulty.

The ammoniacal solution produced smells exactly similar to the ammonia extracted from chloride of ammonium treated with aqua regia, or from sulphate of ammonium treated while hot with a mixture of sulphuric and nitric acids.

These three ammonias, though identical with each other, differed very considerably as to smell from the pure ammonia obtained from commercial chloride or sulphate of ammonium, both of which contain compound ammonias, that give it a disagreeable smell, whilst the smell of pure ammonia is simply pungent. I have already mentioned these facts in my previous work on the same subject.

To transform the dissolved ammonia into chloride, I passed through the solution a current of pure hydrochloric acid until the liquid was nearly saturated. I then evaporated the saline liquid on a water-bath, and finished drying it on a stove. This chloride of ammonium was of a dazzling whiteness. I proceeded to *sublime it in a large platinum retort*, purified at a red heat with chloride of ammonium. To exclude the air from the retort, I passed through it, during the volatilisation, a very slight current of dry ammonia. This precaution is absolutely indispensable, since, in the presence of air and of heated platinum, the vapour of sal ammoniac will readily produce nitric acid and afterwards chlorine.

The volatilised chloride of ammonium covered the upper portion of the head of the retort, in the form of a compact, crystalline, colourless, transparent ring half a centimetre thick, whilst the head and neck were filled with chloride of ammonium, as a fine dust of a dazzling whiteness. Both exhaled a strong ammoniacal smell.

Before being used to determine the proportional ratios, the compact and the powdered chloride were heated in the same apparatus in which they were weighed, until they gave off vapours of sal ammoniac, so as to eliminate the last traces of condensed ammonia.

Preservation of Sulphuretted Hydrogen Solution in the Laboratory.

At the last meeting of the Pharmaceutical Society of Paris, M. Lepage, of Gisors, brought forward a process which he has adopted for preserving solutions of sulphuretted hydrogen. All chemists know that this useful reagent cannot be preserved long in aqueous solution. The author has adopted for some years an artifice which enables sulphuretted hydrogen solution to be kept for twelve or fifteen months with scarcely any loss of strength. Instead of using water, he saturates a mixture of equal parts of pure glycerin and water with sulphuretted hydrogen gas, and uses it in the ordinary manner. None of the reactions are interfered with in the least, whilst the solution possesses almost perfect stability. The dilute glycerin dissolves less gas than distilled water will; representing the solubility in the latter liquid by 100, that in the former will be 60.

Glycerin likewise prevents solution of sulphide of ammonium from becoming coloured, and M. Lepage believes that it has a similar action on the sulphides of potassium and sodium.

---

[*] Zinc may be deprived of carbon by fusion with 5 per cent. of its weight of litharge. The alloy of zinc and lead thus produced is as effectual in reducing nitrite of potassium in the presence of iron as pure zinc. In the presence of dilute sulphuric and hydrochloric acids, it disengages hydrogen with great facility.

On the Classification of Native Silicates,* *by* William Odling, *M.B.*, *F.R.S.*

Again, the function of aluminium or alumina, in some particular silicate, is occasionally open to considerable question. Aluminium salts, it is well known, are derivable from acids, either by the substitution of an atom of aluminium, Al''', for three atoms of hydrogen, as in ordinary alum $Al'''KS_2O_8.6Aq$; or by the substitution of an atom of aluminyl $(AlO)'$ for one atom of hydrogen, as in ordinary acetate of aluminium (the soluble diacetate of Crum) $C_2(AlO)'H_3O_2.2Aq$, or $Al'''\ O''(CH_3O_2)'.2Aq$. In the majority of aluminium-silicates, the aluminium would seem to play the same part that it does in ordinary alum, while in others it may not improbably function as aluminyl. Thus by viewing cyanite and topaz as aluminylic silicates, their anomalous formula $Al_2O_2.SiO_2$, would become reducible to the metasilicate type, and appear as

$$(AlO)_2O.SiO_2, \text{ or } (AlO)_2SiO_3;$$

while euclase would become an orthosilicate, thus—

$$(AlO)_2G_2O_4.Si_2O_4, \text{ or } (AlO)_2H_2G_2O_4.Si_2O_4.$$

But aluminium is not only capable of acting in two distinct fashions as a base, but it can also play the part of an anhydride corresponding to silica. Spinelle, $MgO\ Al_2O_3$, and augite, $MgO.SiO_2$, for instance, may be regarded as analogous, though heteromorphous compounds; and it has been contended by Bonsdorff and others, with considerable show of reason, that in the aluminous augites and hornblendes, the alumina does not act as a base to the silica, but is substituted for a variable amount of the silica isomorphously. Similar remarks apply to boric oxide, B_2O_3, which, in some silicates, as axinite, appears to replace a variable but small proportion of basic alumina or alminyl, while in others, it obviously fulfils the functions of an anhydride, as in datolite and botryolite.

$$Ca''_2H_2\left\{\begin{matrix}B_2O_4\\Si_2O_6\end{matrix}\right. \qquad Ca''_2H_2\left\{\begin{matrix}B_2H_2O_6\\Si_2O_6\end{matrix}\right.$$

In the great majority of well-defined aluminous double silicates, the ratio of monad and diad to triad or pseudo-triad metal is either the spinelle ratio

$$M''O \text{ to } Al_2O_3.$$

or else the cryolite ratio

$$M''_3O_3 \text{ to } Al_2O_3,$$

as exemplified below:—

Spinelle Silicates.

Ortho.	$CaAl_2O_4.Si_2O_4$	Anorthite. Wernerite.
$\frac{1}{1}$	$CaAl_2O_4.Si_2O_4.2Aq$	Thomsonite.

	$Na_2Al_2O_4.Si_4O_8.5Aq$	Phillipsite.
	$CaAl_2O_4.Si_4O_8.6Aq$	Chabasite.
Sesqui.	$K_2Al_2O_4.Si_6O_{12}$	Felspar. Orthoclase.
$\frac{1}{3}$	$Na_2Al_2O_4.Si_6O_{12}$	Albite.
	$CaAl_2O_4.Si_6O_{12}.3Aq$	Parastilbite.
	$CaAl_2O_4,Si_6O_{12}.5Aq$	Epistilbite. Heulandite.
	$CaAl_2O_4.Si_6O_{12}.6Aq$	Stilbite. Desmine.

Cryolite Silicates.

Basic.	$Ca_3Al_2O_6.Si_2O_4$	Gehlenite.
$\frac{3}{2}$	$Fe_3Al_2O_6.Si_2O_4$	Aphrosiderite.
	$G_3Al_2O_6.Si_2O_4$	Euclase.
Ortho.	$Ca_3Al_2O_6.Si_3O_6$	Garnet. Idocrase.
$\frac{1}{1}$	$Mg_3Al_2O_6.Si_3O_6$	Allanite. Orthite.
	$(NaCa)_3Al_2O_6.Si_3O_6$	Sarcolite.
	$(HCa)_3Al_2O_6.Si_3O_6$	Prehnite.
Para.	$Mg_3Al_2O_6.Si_4O_8$	Mica?
Meta.	$G_3Al_2O_6.Si_6O_{12}$	Beryl.

Other ratios are, however, occasionally met with, as in the following examples, and particularly the mixed ratio $MO + M_2O_3$ to $2Al_2O_3$, and the double ratio $2M_2O_3$ to Al_2O_3:—

Para.	$K_3Al_6O_{10}.Si_6\ O_{12}$	Potash-mica.
"	$Mg_4Al_4O_{10}.Si_6\ O_{12}$	Magnesia-micas.
"	$K_2Mg_3Al_4O_{10}.Si_6\ O_{12}$	
	$(LiK)_2Mg_3Al_4O_{10}Si_6\ O_{12}$	Lepidolite.
"	$Ca_4(AlB)_4O_{10}.Si_6\ O_{12}$	Axinite.
"	$Ca_6Al_2O_9.Si_6\ O_{12}$	Humboldtite.
Meta.	$H_{12}Al_2O_9.Si_9\ O_{18}$	Cimolite.
Ortho.	$Ca_6Al_8O_{18}.Si_9\ O_{18}$	Epidote.
Meta.	$Li_6Al_8O_{15}.Si_{15}O_{30}$	Spodumene Triphane.
Anhy.	$(LiNa)_6Al_8O_{15}.Si_{30}O_{60}$	Petalite.

(δ) Among so-called hydrated silicates, the determination of the function of the constituent hydrogen is often a matter of considerable difficulty. It is clear that this hydrogen sometimes exists in the form of water of constitution or crystallisation added to the proper silicate molecule, whereas in others it exists as basic hydrogen, forming an integral part of the silicate molecule; but the means for determining the particular cases in which it exists in the one state or the other, or in both states simultaneously, are usually very imperfect, and sometimes entirely wanting. Dioptase, for example, may either be considered as an orthosilicate of hydrogen and copper, $H_2Cu''SiO_4$, or else as a hydrated metasilicate of copper, $Cu''SiO_3.Aq$, and so in many other instances.

The isomorphism of basic hydrogen with certain basic metals, and more particularly with magnesium, though scarcely established beyond question, is warranted by many facts relating to hydrated silicates. Thus, in several definite silicates, while the proportion of constituent hydrogen is very variable in different specimens, yet, reckoning this hydrogen as basic water, the ratio of the oxygen of the united bases to the oxygen of the silica is almost constant, and identical with the ratio of some typical compound. A variety of talc, for instance, is sometimes represented by the anomalous formula—$Mg_6O_6.Si_7O_{14}.Aq$; but, bearing in mind the temperature required to render such talc anhydrous, it can scarcely be doubted that its proper formula is really

$$H_2Mg_6O_7.Si_7O_{14};$$

or, seeing that the proportion of hydrogen is variable in different specimens, $(HMg)O.SiO_2$.

Prehnite, again, is usually expressed by the formula $Ca_2Al_2O_5.Si_6O_{12}.Aq$; but, independently of the exceptional ratio of lime to alumina, and of base to silica shown by this formula, in reality the proportion of hydrogen or water in different specimens of prehnite varies very considerably. But reckoning the hydrogen or water as basic, the oxygen of the united bases is to the

---

* Dr. Odling has kindly given us permission to publish occasional chapters from the forthcoming second part of his "Manual of Chemistry."—Ed. C. N.

oxygen of the silica exactly in the ratio $\frac{1}{1}$, and the oxygen of the triad to that of the joint diad and monad bases approximately in the ratio $\frac{1}{1}$ also. Similarly, in the different varieties of mesotype, there often exists, in addition to the water formulated as water of crystallisation, a variable small excess of water which contributes to furnish the full complement of base appertaining to the particular silicate.

(ι) It is well known that the production of crystals, either by way of fusion or solution, is much affected by the presence of different impurities, dissolved or suspended in the crystallising liquids, and that, as a rule, the finest crystals are obtained from impure liquids, and carry down with them a certain proportion of impurity. Now, native silicates have all the character of crystals formed from impure liquids, and undoubtedly do contain, in many instances, a greater or less amount of accidental impurity. Chabasite, for example, frequently contains an excess of uncombined silica, with which, indeed, it is isomorphous; while some crystals of augite are said to contain a small proportion of garnet; and similarly in several other cases. Moreover, it is not improbable that certain definite silicates may contain variable proportions of other silicates—that a spinelle-silicate, for instance, may contain some cryolite-silicate, and a metasilicate some sesqui-silicate—in a state of perfect homogeneity, and without affecting their special crystalline forms; just as the heteromorphous alloys, Sb_2Zn_3 and Sb_2Zn_2, may each contain a not inconsiderable proportion of the other, without prejudice to the distinctive character of their respective crystalline forms. Altogether, while the analysis of artificial compounds is habitually preceded by their elaborate purification, that of native silicates is performed at once upon compounds never free from more or less accidental impurity, which, occurring in an otherwise definite silicate, may interfere very seriously with the right interpretation of the results of its analysis.

(ζ) Lastly, considering the number of operations to be performed, and of precautions to be taken, in order to obtain an accurate estimation of some one constituent only of an ordinary silicate—such as the alumina, or magnesia, or soda—it is evident that the difficulty and complexity of the processes employed in the complete analysis of most native silicates must be considered as detracting somewhat from the absolute certainty of even the percentage results arrived at. To this consideration may be added the probability, insisted upon by Laurent, that the few tenths or even hundredths of water contained in many silicates, and frequently disregarded both in the statement of results and calculation of formulæ, may sometimes, at any rate, fulfil a very important function in the constitution of the several minerals, and permit the association of their respective formulæ with those of well-recognised typical compounds.

Bearing in mind, then, the many circumstances interfering with the accurate determination of their molecular composition, it would appear that the actual types of native silicates are much fewer and simpler than is generally supposed; and, that in the great majority of instances, where the chemical formula of a mineralogically well-defined silicate is deduced from the analyses of a considerable number of different specimens, the ratio of the oxygen of the alumina to the oxygen of the other bases will prove to be either the spinelle or the cryolite-ratio, or occasionally that of some closely related compound; while the ratio of the oxygen of the silica to the oxygen of the united bases will prove to be that of an ortho-, para-, meta-, or sesqui-silicate; and that in the majority of instances, where these ratios are seemingly departed from to some extent, the departure will be found really due to a partial substitution of alumina for some stronger base on the one hand, or for some silica on the other; or to a nonrecognition of some constituent water; or the presence of some accidental impurity or intermixture. Altogether it is evident that a considerable latitude must for the present be permitted in the assignment of formulæ to complex native silicates, and especially to those of which but a few specimens have been submitted to careful analysis.

On the Purification of Chloride of Ammonium by Volatilising it in a Vacuum, by Prof. J. S. Stas.

The following is the method employed for the volatilisation of sal ammoniac in a vacuum:—

Forty grammes of chloride of ammonium obtained by the direct combination of hydrochloric acid with the ammonia produced by the reduction of nitrite of potassium, were introduced into a glass tube, ninety-five centimetres long and three centimetres in diameter, closed at one end and open at the other. The chloride, first well dried, being placed at the closed end, I placed the tube in a horizontal position on the metallic support of a gas jet; I put the open end against another open tube of the same diameter, and placed over the junction a glass tube of ten centimetres diameter, which I fixed with a cement of gum lac, letting some of the cement run between the tube and the two juxtaposed portions. To the second tube there was joined a T-shaped tube, whose very short, almost capillary branch went to the branch of a steel tap in which I luted it hermetically with a resinous cement. The vertical branch of the T tube plunged into a test-tube containing mercury. Into the other branch of the tap I cemented a capillary tube in communication with a pneumatic machine capable of making a vacuum in the apparatus of 0·0005 m. To prevent the sal ammoniac, which, in a vacuum, condenses as an impalpable powder, from penetrating into the almost capillary tube and blocking it up, I filled the large tube, to which the T tube was joined, with a brush of fine platinum wires, preceded by a large quantity of calcined and still warm asbestos. Before commencing the sublimation of the sal ammoniac, I made sure that the apparatus kept a vacuum for twenty-four hours. I then proceeded to the volatilisation. For this purpose I heated directly in a gas flame the part of the tube containing the sal ammoniac, *taking the precaution of keeping the temperature as low as possible.* During the sublimation the mercury continually oscillated in the vertical branch of the T tube, and the chloride condensed partly as dust and partly as a thick colourless ring. After the tube was cool enough for all tension to be removed from the sal ammoniac, the mercury rose in the tube to the same level as before the operation—a proof that no gas was formed during the sublimation but what was condensed afterwards. I made a second and then a third volatilisation of the same sal ammoniac. During the two latter volatilisations I took care to keep the air-pump continually at work, so as to carry off any gas that might be produced.

After the tube was quite cold, the sal ammoniac, which was sublimed in a compact ring, detached itself noisily from the tube, becoming at the same time opaque instead of transparent and highly refracting, as it was whilst hot.

I determined separately, and as they came from the tube, the proportional ratio of the sal ammoniac in a compact mass and in impalpable dust. Both contained traces of sodium, which, however, could only be appreciated by spectral analysis; they probably acquired this metal from the ordinary white glass tube, in which the triple volatilisation was performed.

On the Direct Production of Stilbene from Bitter Almond Oil, by C. Greville Williams, *F.R.S.*[*]

Stilbene was obtained by Laurent by the distillation of hydride of sulpho-benzoyle, according to the equation—

$$\underbrace{8C_7H_6S}_{\text{Hydride of sulpho-benzoyle.}}=2CS_2+3H_2S+\underbrace{2C_{14}H_{12}}_{\text{Stilbene.}}+\underbrace{C_{26}H_{18}S}_{\text{Thionessal.}}$$

The simplicity of the relation between hydride of benzoyl and stilbene made me conceive that the latter might be produced directly from the former; thus—

$$2C_7H_6O+4Na=C_{14}H_{12}+2Na_2O.$$

Experience has completely confirmed this supposition. The reaction, however, as might be expected, does not take place without the formation of other products. In fact, the amount of stilbene produced is so small, and the difficulties in the way of the separation of the substances produced are so considerable, that I should have delayed publishing my results in their present state had I not seen that Claus[†] is working in a somewhat similar direction. However, as he employs sodium amalgam and an etherial solution of hydride of benzoyl, instead of hydrocarbons, he obtains bodies containing oxygen. One of the substances produced in the manner indicated is the salylic acid, $C_7H_6O_2$, of Kolbe and Lautemann, and the other appears to be identical with Church's dicresol, C_7H_7O.[‡]

To obtain stilbene I treated the bitter almond oil of commerce with an equivalent quantity of sodium, and distilled the mixture at a temperature sufficiently high to bring over everything volatile. The distillate was again treated with sodium and fractionally distilled. One portion came over below 200°, and contained volatile liquid hydrocarbons, among which benzol was observed. The fraction distilling between 200° and 244° did not yield any crystals, even when exposed to a freezing mixture of ice and salt. That portion of fluid which distilled between 244° and 265° became nearly solid on cooling. Above 265° the distillate consisted chiefly of crude stilbene. The fluid distilling between 200° and 244° contained carbon 85·3, hydrogen 8·1, oxygen 6·6. It was apparently a mixture, and probably contained a small quantity of stilbene in solution.

The solid substance was dissolved in hot benzol, and on cooling gave a crop of beautiful colourless prismatic crystals, which, when perfectly freed from benzol by exposure for some time to a temperature of 100°, gave the product *a*. The mother liquid, on standing, gave a second crop *b*, which was freed from benzol in the same manner as the first. The third crop *c* was only purified by pressure between folds of filtering paper. The residue, evaporated to dryness and sublimed, gave crop *d*. The melting points were as follows:—

a	113°
b	116°
c	78°
d	100°

The second crop was burned with oxide of copper and oxygen gas, with the annexed result:—

0·2227 gramme of crop *b* gave
0·7642 " carbonic anhydride, and
0·1374 " water.

Or, per cent.:—

	Experiment.	Calculation.	Stilbene.	
Carbon	93·59	93·33	C_{14}	168
Hydrogen	6·85	6·67	H_{12}	12
		100·0		180

Agreeing, therefore, with the formula $C_{14}H_{12}$, which is that of stilbene.

The melting point of the specimen analysed was 116°. Laurent does not give the melting point of stilbene, but merely states that it fuses several degrees above 100°.

The vapour density of stilbene as given by Laurent is 8·4, a number which is entirely incompatible with the formula. Therefore, although I only had a very minute portion (less than two decigrammes) of stilbene left, I resolved to repeat the vapour density determination, feeling sure that even if the experimental result was not so accurate as might be desired, it would still be a sufficient approximation to indicate the true formula of the substance analysed. The experiment was made in an atmosphere of mercury vapour, with the annexed result:—

Excess of weight of balloon	0·1371 gramme.
Temperature of vapour	350°
Temperature of air	17°
Pressure	764 m.m.
Capacity of balloon	95·5 c.c.
Residual air	12·5 c.c.

Experiment.	Calculation.
6·024	6·228

The large amount of residual air, and the smallness of the scale on which the experiment had to be made, make me regard this experiment as one requiring to be repeated. It is, however, quite near enough to the theoretical value to show that the number obtained by Laurent was due to some error of experiment.

It is important to observe that the specimen of stilbene which fused at 116° had its melting point raised to 120° by keeping it for some hours at a temperature of 100°. It is evident, therefore, that the fusing point of stilbene is not lower than 120°.

Recent Analysis of the Montpellier Saline Chalybeate (Kissingen) Spring at Harrogate, by Dr. Sheridan Muspratt, *M.D. (Hon.), F.R.S. Ed., M.R.I.A., &c.*[*]

As there have been so many strange analyses, some most conflicting, of the water of the above celebrated spring, I have for some months been engaged with experiments and researches upon it; and feeling that the results elicited are now the true ones, I place them before the readers of your ably conducted journal. In

[*] Communicated by the author.

the Chemical News for June 29, of last year, it is stated that this Kissingen spring holds the following:—

Carbonate of baryta....................	7·657
Carbonate of strontia..................	2·815

Neither of these earthy carbonates is contained, as such, in the water. The barium exists as a chloride—*i.e.*, in the same form as it does in the "Dr. Muspratt chalybeate, or chloride of iron spring." Annexed is the new analysis, collaterally with that of my friend Dr. Hofmann:—

	Grains in the imperial gallon.	
	1854. Dr. Hofmann.	1867. Dr. Muspratt.
Carbonate of iron........	2·790	3·719
Carbonate of lime........	—	21·011
Carbonate of magnesia...	41·796	2·074
Carbonate of manganese..	trace	trace
Chloride of sodium......	656·838	700·500
Chloride of calcium.....	159·278	168·450
Chloride of magnesium..	35·635	81·560
Chloride of potassium...	11·383	6·916
Chloride of barium......	—	6·364
Chloride of strontium...	—	traces
Chloride of lithium......	—	traces
Silicic acid.............	0·947	0·438
Ammonia, &c...........	traces	traces
	908·667	991·032

Cubic Inches of the Gases in One Gallon of the Water.

Carbonic acid...................	24·17	21·33
Carbide of hydrogen..........	2·40	2·74
Oxygen.........................	·51	·77
Nitrogen........................	6·48	5·92
	33·56	30·76

The quantity of chlorine in the gallon was estimated by my assistant, my brother Edmund, five other chemists, and myself, and the mean (by weight and volumetrically) was 596·472 grains per gallon. The total amount of chlorine, in June, 1865, was 510·17 grains per gallon; in March, of this year, I found 592·5 grains. From the recent analysis, the water is much stronger in its saline ingredients; besides, it has acquired others (chlorides of barium, &c.) that did not exist in it previously. When the late Mr. West, of Leeds, analysed the water from this spring many years ago (1844?), he gave 20 grains of sulphate of soda in the gallon. If this salt was present then—it could not possibly be there with chloride of barium—it is not now found in any of the strongly impregnated waters of Harrogate, "the queen of northern spas," as justly styled by Dr. Granville. The springs to which Harrogate owes its celebrity exceed in number those of any other place in the kingdom.

College of Chemistry, Liverpool, May 1.

On the Direct Estimation of Boracic Acid, by Professor F. Wöhler.

In order to estimate directly the boracic acid contained in datolite, $3(CaO,BO_3)+3CaO,3HO,4SiO_3$, place the mineral in a small tubulated retort, decompose it with hydrochloric acid, and distil the mixture to dryness; pour on to the residue the distillate (which contains boracic acid), and allow it to digest to separate the silica. In the liquid precipitate the lime by means of oxalate of potash, taking care not to add it in too great excess. Then, after filtration and concentration, precipitate the boracic acid in the form of double fluoride of boron and potassium. For this purpose, add a little potash to the material in a platinum capsule, then pour over the mixture a slight excess of hyprofluoric acid, and evaporate the solution to dryness. To remove the other salts it suffices to treat the mass with a moderately concentrated solution of acetate of potash; then allow it to digest and throw on to a filter the double fluoride of boron and potassium, and wash it with the same solution of acetate. Then wash with dilute alcohol to remove the acetate of potash; the double fluoride is then dried at 100° C, and weighed.

On Determining the Proportional Relation between Silver and Chloride of Ammonium, by Professor J. S. Stas.

The method of determination I used is that described in my former article. To prevent the loss of hydrochloric acid, which would have been set free by introducing chloride of ammonium into a hot acid solution of nitrate of silver, I neutralized with pure ammonia the excess of nitric acid used for dissolving the silver. The following is the manner in which I proceeded:—

After having added to the solution of silver in nitric acid 100 *cubic centimetres of water for each grain of metal* dissolved, I poured in, drop by drop, a solution of pure ammonia. When the liquid was alkaline, I neutralised it by a suitable addition of *pure acetic acid.*

In order that the double decomposition might take place under absolutely identical conditions, I neutralised with ammonia both the silver solution to be precipitated while cold, and that at 100°. In order that the solution should be about 100° at the moment of the double decomposition, I kept the flask or globe in which the assay was made in boiling water *for two hours*, and without removing it from the bath I introduced the chloride of ammonium. As the precipitation took place at a high temperature, the liquid cleared itself the moment a complete mixture of the reagents had taken place.

I weighed in air[*] the chloride of ammonium and the silver employed, assuming, according to Prout's hypothesis, the weight of the molecule of chloride of ammonium to be 53·50, and that of silver 108·00. The excess of the metal remaining in the liquid after the double decomposition was determined without removing the flask or globe from the bath. For this purpose I directed a pencil of yellow light to the surface of the liquid in which I wished to measure the silver. The comparative assay, made at the ordinary temperature, was performed by means of the apparatus for *titration*, described on page 137.

The following table contains the results of these three sets of experiments. I have added three determinations taken from my former work; they were made with chloride of ammonium produced at the ordinary temperature by combining directly solutions of ammonia and hydrochloric acid:—

---

[*] To reduce to a vacuum the chloride of ammonium weighed in air, I weighed in the air and *in vacuo* a portion of the sal ammoniac that I intended to use. These assays convinced me of a fact that had already been stated by M. Marignac—viz., that the augmentation of weight obtained by weighing the pulverulent chloride directly *in vacuo* was always less than would have been calculated from the density. I found that 100,000 parts of pulverulent chloride weighed in air represented from 100,077 to 100,084 parts of the same compound weighed *in vacuo*. M. Marignac gives the figure 100,080 as the mean of the extremes. These weighings also showed me that the density of compact sal ammoniac differs appreciably according as it is transparent and vitreous, or opaque and amorphous.

Proportional Relation between Silver and Chloride of Ammonium.

Number of the experiment.	Weight of the sal ammoniac reduced for a vacuum.	Weight of the silver reduced for a vacuum.	Weight of the excess of silver after the double decomposition.	Chloride of ammonium which is equivalent to 100,000 parts of silver.

IX.	6·2250	12·5663	0·0140	49·592

The results given in the preceding table prove that, within the limit that must be allowed in making the experiments, *temperature exercises no influence upon the composition of chloride of ammonium or of chloride of silver; they prove further that pressure is without any influence upon the composition of chloride of ammonium.* In fact, whatever may be the mode of preparation of the compound of ammonium, and the temperature at which the double decomposition takes place, *its proportional relation to silver is constant.*

If the admitted constancy of the stable chemical combinations required to be demonstrated, it seems to me that the almost absolute identity of the results of the four series of determinations is sufficient to prove it. This constancy is the more remarkable, since sal ammoniac can, as I have observed, condense ammoniacal gas or hydrochloric acid, *in the same way that a number of bodies condense gases and vapours completely foreign to them in their constituent elements.*

Among the twelve determinations given in the table there is one, No. II., which was made upon a quantity of material such as was never before employed in an experiment of this kind. I had a double object in using such large proportions. I wished to render sensible the influence of temperature upon the composition of chloride of silver, if there were any such influence; and then, as I was working with chloride of ammonium that had been sublimed three separate times, twice in vessels of *hard glass*, not attacked by the vapour of chlorine, it should be of an extraordinary purity,* and I ought to be able to deduce an important consequence with reference to the hypothesis of Prout. Now, after the double decomposition had taken place upon the weights calculated according to Prout's hypothesis, there remained dissolved in the liquid 0·097 gr. of silver, being a quantity *one hundred times* greater than that which I could have appreciated in the mass of liquid, and certainly *fifty times* greater than it is possible to measure by taking the trouble.

I invite those who think they can attribute "to errors of observation" or "to the impurity of the materials"* the differences observed between the experiment and Prout's hypothesis, to take the trouble of repeating, under the conditions necessary for exactitude, the determination of the proportional relation between chloride of ammonium and silver, and I shall wait with entire confidence the result of their investigation.

In speaking thus I do not pretend that the figures I have given are absolutely exact—that is to say, that they may not be affected by a constant error. I am even sure of the centrary, and in the conditions in which I was placed the constant error must have attained its maximum. In fact, the operation for deducing the proportional relation between the chloride and the silver involves an uncertainty to which I have already drawn the attention of chemists in my "*Recherches sur les Rapports Réciproques des Poids Atomiques.*" This uncertainty consists in the fact that an argentiferous liquid, from which nearly all the metal has been precipitated by a solution of chloride of potassium, sodium, or ammonium, but which still contains one or two milligrammes of silver per litre, precipitates both on the addition of a normal solution of silver and of alkaline chloride. I find this phenomenon is the more pronounced the less acid the liquid is, and the more alkaline nitrate it contains. Now, in the double decompositions between nitrate of silver and chloride of ammonium, I was obliged, for the reason given above, to neutralise the excess of nitric acid by ammonia, and, for the same reason, I only added a slight excess of acetic acid. The conditions, then, which are the primary cause of the uncertainty, are both present, and they must, as I have said before, bring the constant error to a maximum. But after allowing very largely for this constant error, there remains such a considerable difference between the calculated and observed results, that it is quite impossible to attribute it to any other cause than to the inexactitude of Prout's hypothesis.

TECHNICAL CHEMISTRY.

On the Discovery of Sulphate of Strontium in Upper Silesia, and its Application in Agriculture, by Geo. Lunge, *Ph. D.*†

The following fact may not be quite uninteresting to such of the readers of this journal as work in agricultural chemistry. In a locality in Upper Silesia there is found a stratum of an earthy mass, similar in colour to chalk, but crystalline under the microscope, which had been taken by the farmers of the neighbourhood for a kind of marl containing gypsum. Many hundred tons of it have been used for years as a manure, and with the best success. Quite lately Professor Krocker, of Proskan, got a sample of this mass, and found it to contain—

---

* These experiments are taken from my former work; the numbers of the experiments have been retained in the table.

* *Cosmos*, vol. xvii. p. 653.

† Communicated by the author.

	Per cent.
Sulphuric Anhydride	36·00
Strontia	46·57
Lime	1·80
Magnesia	1·60
Potassa	0·50
Chloride of sodium	0·25
Carbonic anhydride	1·40
Phosphoric anhydride	0·10
Silicic anhydride	2·10
Alumina and ferric oxide	3·60
Clay, sand	4·28
Moisture and organic substances	1·80
	100·00

The mineral is, then, essentially sulphate of strontia, and it is remarkable that it has proved of some value as a manure, notwithstanding the very slight solubility of that body, and although it cannot be supposed that strontium can absolutely substitute calcium in the plants.

On the Waste of Materials in the Alkali Manufacture, by James Hargreaves.*

In the manufacture of carbonate and hydrate of soda from its sulphate there is a very considerable loss of material, which renders the actual produce very considerably less than is indicated by theory. This loss of course varies in different manufactories, according as care and skill are exercised to reduce it, or the work is carried on carelessly and at haphazard. The reduction of this loss is not only of individual, but of national importance, inasmuch as the glass, soap, paper, and other manufactures having the most immediate influence on civilization and comfort, depend for their existence and extension on a large and cheap supply of this alkali. The usual method of estimating the alkali produced from the crude sulphate of soda or "salt cake" is to multiply the weight of soda ash produced from every 100 tons of salt cake by the percentage of alkali contained in it, and divide these integers by some standard number—say, 48, 50, or 52, which gives the number of tons of ash of the standard strength from each 100 tons of salt cake used. Theoretically, 100 tons of salt cake, containing 96 per cent. of sulphate of soda, or 42 per cent. of the base, should produce 84 tons of soda ash of 50 per cent. The following list of practical results shows how different manufacturers fall short of the theoretical yield:—

	Ash from 100 parts of salt cake.	Standard percentage of ash.	Equal to alkali produced per cent.	Total loss per cent.
Soda ash	75	50	37·5	10·72
	70	52	36·4	13·44
	70	50	35·0	16·66
	66·66	52	34·67	17·46
	70	48	33·6	20·00
	66·66	50	33·33	20·65
Caustic soda	57·5	60	34·5	17·86
	55	60	33·0	21·20
	50	60	30·0	28·57

The sources of this loss are as follows:—

1. **By soda salts carried mechanically into the flues and chimney.**—I am not aware that any attempts have ever been made to ascertain the quantity thus carried away, but it must be very considerable, more than is generally suspected. Where salting pans are used, and the hot gases from the black-ash furnace are passed over the crude soda solution to partially carbonate and dry it to "salts," this salt and the "red liquor" drawn along with it generally contain from 0·25 to 1 part of sulphate of soda to every 100 parts of available alkali, more than is contained in the crude soda liquor when run into the pan; the proportion varying with the elevation of the furnace bed, the intensity of the draught, and the mechanical division of the sulphate. But this does not represent the whole of the sulphate thus carried away unutilised, the finer particles being carried beyond the pan into the flues and chimney. In the "finishing furnace," where the "black-ash salt" is heated to dull redness, to expel water, burn out carbonaceous matters, and oxidise the sulphide of sodium present, converting it into sulphate of soda; there is also a small quantity carried away in this manner, as is shown by the glazing of the bricks and deposit of alkaline dust in the flues.

2. **By volatilisation of sodium salts.**—A more considerable loss of material is sustained by the volatilisation of sodium, principally as sulphide and carbonate. The workman generally prefers to work with his furnace very hot, so as to get out his complement of "balls" as soon and with as little labour as possible. The temperature of the furnace is generally below the boiling point of any of the sodium salts present, but when a rapid current of hot gas is passing over and given off from the materials, these salts are absorbed and carried off as vapour, the action of the hot gas in this case being analogous to that of a current of air in drying up water or other volatile fluids when far below their boiling points. When the door of the lower bed of the furnace is opened while the temperature is high, a white cloud, containing sulphate and carbonate of soda may be seen rising from the bed. The sulphate is produced by the oxidation of volatilised sulphide, in consequence of the in-rush of cold air through the door, which at once oxidises the sulphide and condenses the alkaline vapours by reduction of temperature. The practical difficulties of the work have so far prevented the estimation of this and the former sources of loss, but comparison of the materials put into and drawn from the furnace leave no doubt that it is very considerable, and varying with the temperature at which the furnace is worked. There is no advantage except that of saving labour and time to the workman in having the temperature higher than is necessary to reduce the sulphate of soda, and cause the sulphide of sodium and carbonate of lime to react on each other. When the temperature is maintained too high, there is not only a great loss by volatilisation, but the increased quantity of fuel used for the purpose is thrown away, the furnace is prematurely worn out, and there is formed at very high temperatures an allotropic sulphide of sodium, which does not react on the lime present in the charge.

3. **By combination of soda with the materials of the furnace.**—This is another, but comparatively small, source of loss. The bricks, &c., taken from the furnace while undergoing repair hold in combination a considerable amount of soda, being in some pieces 6 per cent. and upwards, but in an insoluble condition, and therefore unavailable. The fused sodium salts which have filtered into the interstices of the furnace are also of no practical utility.

4. **By the formation of insoluble compounds of soda,** which, by rendering impossible the extraction of the alkali by lixiviation, still further diminishes the yield. The small coal, which is used as a reducing agent,

---

* Communicated by the author.

invariably contains more or less ash, varying from 1·5 to 8 per cent. Of this ash silica and alumina form a large proportion, seldom less than 80 per cent. of the whole. The salt cake contains from 0·12 to 0·5 per cent. of silica and alumina, and the limestone from 0·2 to 3 per cent. These form with soda a compound silicate, which is sparingly soluble in a solution of caustic soda and sulphide of sodium. When the crude soda solution is oxidised, and the sulphide converted into hyposulphite, sulphite, or sulphate of soda, or when it is exposed to a temperature of 212° F., the alumino-silicate is precipitated. In the oxidising apparatus described in the Chemical News, No. 340, the precipitate is in the form of a white powder; and in oxidising towers, where the solution is oxidised by running it over pieces of coke, to expose a large surface of the fluid to the action of the atmosphere, the alumino-silicate is deposited on the coke, filling up its interstices, and if not frequently disturbed by taking the coke out at the bottom of the tower, washing and returning it to the top, the whole is in time converted into a firm cohesive mass. Another compound silicate of soda and lime is formed when the silica is in excess of what is required to form the alumino-silicate, and is quite insoluble. The loss from this cause is variable in proportion to the quantity of alumina and silica introduced along with the materials used and the quantity of these substances taken from the bricks of the furnace.

5. **By non-decomposition or imperfect decomposition of sulphate of soda.**—The loss from this cause varies considerably in different manufactories. In some the average quantity of sulphate, or its equivalent in sulphate with sulphide, &c., is as 5 of sulphate to every 100 parts of available alkali, which is equal to a loss of 2·19 parts for every 100 parts of sulphate made available. In others (where the works are too small to afford, or the managers are too "economical" to employ, scientific supervision) the loss not unfrequently averages 24 parts of sulphate to every 100 parts of available alkali, by which 9·22 parts of the sulphate remain unavailable for conversion into carbonate for every 100 utilised. The loss from this cause generally varies between these proportions, more frequently exceeding the latter than going below the former.

The sulphate may remain unaltered in consequence of deficiency of carbonaceous matter, too low temperature of the furnace, or insufficient or unskilful working; or the decomposition may have only proceeded so far as to produce sulphide of sodium, without reacting on the carbonate of lime used in mixing the charge. This is the result of either a deficient quantity of carbonate of lime or bad working in the furnace.

When the crude soda or "black ash" is exposed to too high a temperature, an allotropic modification of sulphide of sodium is formed. This modified sulphide does not react on the lime present in the charge, but remains unchanged, and the black ash, instead of a grey, is of a dull brick-red colour, and forms a blue solution with water. When chlorine is passed through a solution from this red ash to convert the sulphide into sulphate, there is only a small portion so converted; the rest of the sulphur from the sulphide is precipitated—not being soluble in the alkaline solution—and may be separated by filtration. By this it is obvious that there is no dependence to be placed on the use of chlorine to convert the whole of the sulphide into sulphate, when the black ash is "burnt," and the loss shown by analysis is less than the real loss.

6. **By Oxidation of crude soda.**—There are some manufacturers who think nothing of allowing the black ash to be exposed for several days to the weather before being lixiviated. When the weather is dry no harm is done, but in wet weather the balls are moistened, and the sulphide of calcium is rapidly converted into sulphite, hyposulphite, and sulphate of lime, which, reacting on the carbonate of soda, forms the corresponding soda salts, while the lime is converted into carbonate. To avoid this the black ash must be kept quite dry, and not kept too long a time, but it should have sufficient time to become quite cold.

This action is also frequently continued in the vats, which being filled too full with black ash, a great quantity is exposed to the air in a wet condition. Each vat should not be filled so full but that the whole of the black ash can be covered with water at once, and never allowed to be uncovered until the vat is spent and run off. The vat liquor contains more sulphate in proportion to the available alkali than is contained in the black ash as drawn from the furnace, in consequence of this oxidising action of the atmosphere. The loss of alkali from this cause is seldom less than 0·2 per cent. of the whole; but I have frequently seen black ash in which the parts most exposed to the weather have had more than one-third of the alkali reconverted into sulphate of soda.

7. **By inversion of the furnace reaction.**—When the water used in lixiviating the black ash is too hot, the furnace reaction is inverted, the sulphur combining with the sodium, and the oxygen and carbonic acid with the calcium—

$$NaOCO_2 + CaS = NaS + CaOCO_2.$$

This reaction takes place more rapidly in weak than in strong solutions, and is therefore more apt to occur where the water is run on the weak vat warm, than when it is warmed by steam in each vat separately, raising the temperature a little in each successive vat till it reaches the strongest one.

If the vats are not perfectly cleaned from the waste from former charges every time they are discharged and filled, the waste remaining, and which has been exposed to the atmosphere, becomes partially oxidised, reacts on the soda solution, and forms soda salts of the sulphur acids, and the whole of the soda thus combined is for all practical purposes lost.

8. **By imperfect lixiviation.**—If an insufficient quantity of water is run through the vats, or the water is too cold, or the vats are worked too rapidly, or the black ash is thrown into the vats in too large lumps, or is deficient in porosity, a considerable quantity of alkali is left in the waste, and thrown away with it.

This loss is greatly increased by having too small a space for lixiviating the black ash, which allows too short a time for extracting its soluble constituents, and necessitates the use of hot water, thereby offering the alternatives of sustaining loss by decomposition of carbonate of soda, or by leaving soda in the waste, or needing a great expense to concentrate the liquor; for if hot water is not used a much larger quantity of water is required to extract the alkali, and as the solution contains a smaller proportion of alkali, the use of a larger quantity of fuel is required to concentrate it. These evils are best overcome by having ample vat space.

The waste should not contain more than 0·1 per cent. of alkali, which is equal to about 0·45 per cent. of the whole alkali originally present in the black ash. But it not unfrequently amounts to ten or even fifteen times this amount where there is no proper supervision of the vats and analysis of the waste.

9. **By spilling, leakage, &c.,** in moving material from place to place. This is a mechanical rather than a chemical question, and how to prevent it is too obvious to require comment.

The foregoing shows that, without any alterations in the principle of Le Blanc's process, there is still a large margin for improvement in the details of the soda manufacture.

Appleton-in-Widnes.

Notes on Thallium and Magnesium Alloys, by S. Mellor, *Esq., Manager of the Magnesium Metal Company.*[*]

It having been suggested that if an alloy of thallium and magnesium could be easily made into wire it might be found to burn readily and to produce an intense bright green flame, which, from its portability, would be well adapted to some of the purposes for which a green flame is required, some experiments have been made with this end in view.

It was found that thallium alloys most readily with magnesium, and in any proportions. The alloys are very stable, and are easily worked up into wire and ribbon. Alloys containing 5, 10, 15, 20, 25, and 50 per cent. of thallium were prepared. These all burn brightly and steadily, but the flame is smaller and the combustion slower than that of pure magnesium. The flame is cold, and the heat-conducting property of the alloy, compared with magnesium, is sensibly diminished, showing the change in the molecular construction of the metal. The smoke produced in the combustion of these alloys is more dense, and as it curls gracefully away it is seen to be fringed with a rather pretty dark purple tint; but the magnesium light is so very intense that it almost completely masks the thallium flame, so that it is not observable in some of the alloys—indeed, the green light is scarcely recognisable even in an alloy containing 50 per cent. of thallium.

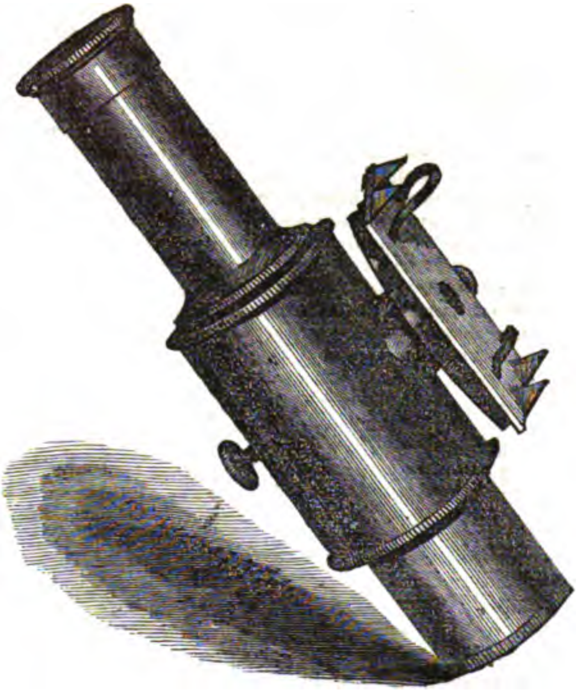
An alloy of 5 per cent. of thallium appears to render magnesium less brittle and more ductile than pure magnesium is usually produced; but the higher alloys of thallium, say those containing 25 and 50 per cent. of thallium, are more oxidisable than pure magnesium.

The metals were put together cold in a closed iron crucible; only a slow heat was required to melt them.

PHYSICAL SCIENCE.

On a New Micro-spectroscope, and on a New Method of Printing a Description of the Spectra seen with the Spectrum Microscope.

In the Chemical News for April and May, 1865,[†] Mr. Sorby, F.R.S., described his application of spectrum analysis to microscopical investigations, and especially to the detection of blood stains. For the purpose for which it was intended, this arrangement was excellent, but in general practice it was in some respects inconvenient. Mr. Browning has recently made for Mr. Sorby a modification of the spectroscope, which is intended to slip into the eye end of a microscope instead of the eyepiece. The instrument is shown in the accompanying figure. It contains a series of prisms arranged for viewing the spectrum by direct vision. The arrangement at the upper part on the right side is for the purpose of obtaining a supplementary spectrum from any object whose spectrum it is desired to compare with that of the object placed on the stage of the microscope. This object may be either a solution of permanganate of potash in a small sealed tube, a cobalt blue glass, or anything else which will furnish a standard spectrum for comparison. There are milled heads with screw motions to adjust the focus of the different parts of the spectrum, and to open and shut the slit vertically and horizontally. Powers of from half an inch to $\frac{1}{20}$th may be employed, and by using a binocular microscope the object may be brought into the field, and examined in the ordinary way through one tube, whilst its spectrum may be observed and compared with that of a standard light by means of the other tube. The object may be illuminated either by transmitted or reflected light, and any of the ordinary accessories may be used for this purpose, such as a chromatic condenser, side reflector, Lieberkuhn, &c.



Mr. Sorby has also introduced a standard spectrum, which he proposes should be used as a scale in all descriptions of spectra, as seen by the spectrum microscope. Mr. Sorby has been good enough to communicate to us the following description of this valuable method:—

The scale adopted is an interference spectrum, produced by a plate of quartz ·043 inch thick, cut parallel to the principal axis of the crystal, and placed between two Nicol's prisms. In this the whole visible space is divided by dark bands into twelve regular divisions, having in all parts the same relation to the physical properties of the light. These are counted from the red end towards the blue, their centres being reckoned as 1, 2, 3, &c., and the thickness of the plate is so adjusted that the sodium line exactly corresponds to 3½. The intensity of the absorption is expressed by the following types:—

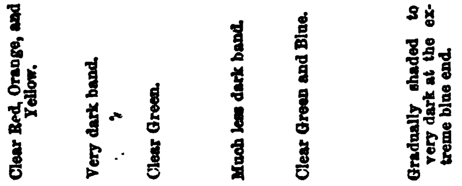
---

[*] Communicated by the author.

[†] Chemical News, vol. xi. pp. 186, 194, 232, and 256.

Not at all shaded	Blank space
Very slightly shaded	. . . Dots with wide spaces
Decidedly shaded	... Dots closer together
More shaded	... Very close dots
Strongly shaded, but so that a trace of colour is still seen	--- Three hyphens close
Still darker	— Single dash
Nearly black	—— Double dash

Except when specially requisite, only the symbols . . . --- — are employed for the sake of simplicity, and then as signs of the relative rather than of the absolute amount of absorption, and it is assumed that there is a gradual shading off from one tint to the other, unless the contrary is expressed. This is done by means of a small vertical line over the figure (see No. 11), which shows that there is a well-marked division between them. Definite narrow absorption bands are indicated by * printed over their centre. This will be better understood by a description of the spectrum of deoxidised hæmatin.



$$4\tfrac{1}{4}\overset{*}{\text{—}}5 \qquad 5\tfrac{1}{2}\overset{*}{\ldots}6\tfrac{3}{8} \qquad 9\,..\,10\text{---}11\text{—}$$

The following examples will show how simple or more complicated spectra may thus readily be printed and compared. I have chosen solutions of similar tint, in order to show that the spectra of those of nearly the same colour may be very different, or, if analogous, may differ in details, easily expressed by the symbols. The colour of each is given after the name. Nos. 1, 8, 9, 10, 11, 12, and 13 can be kept for a long time, sealed up in tubes, and the rest are easily prepared.

1. Cudbear in alum (pink): 3 . . . . . 8 11 . —

2. Colour of elder berries with citric acid (red pink):—

$$4\,.\,\text{-}\,5\tfrac{1}{4}\text{—}8\text{--}9\,.\,.\,.\,11.\text{-}\text{—}$$

3. Brazil wood with bicarbonate of ammonia (pink):—

$$4\tfrac{1}{2}\overset{*}{\text{—}}5\tfrac{3}{4}\,.\,.\,.\,.\,.\,.\,8$$

4. Logwood with bicarbonate of ammonia (pink):—

$$3\tfrac{5}{8}\overset{*}{\text{—}}5\tfrac{1}{4}\,.\,.\,.\,.\,.\,.\,7$$

The next four are spectra of blood, produced by the successive addition of the various reagents, as in detecting fresh stains.

5. Fresh blood (pale scarlet):—

$$3\tfrac{1}{2}\overset{*}{\text{—}}4\tfrac{3}{8} \quad 4\tfrac{3}{4}\overset{*}{\text{-}}5\tfrac{3}{4} \quad 7\,.\,.\,8\text{-}9\text{—}$$

6. Citric acid then added (pale brown):—

$$1\tfrac{5}{8}\overset{*}{\ldots}2\tfrac{1}{4} \quad 4\ldots8\ldots9\text{---}10\text{—}$$

7. Ammonia then added (pale brown):—

$$3\tfrac{5}{8}\overset{*}{\ldots}4\tfrac{3}{8} \quad 4\tfrac{7}{8}\overset{*}{\ldots}5\tfrac{5}{8} \quad 7\,.\,.\,8\text{---}10\text{—}$$

8. Deoxidised hæmatin, from blood stain two years old (pink):—

$$4\tfrac{1}{4}\overset{*}{\text{—}}5 \quad 5\tfrac{1}{2}\overset{*}{\ldots}6\tfrac{3}{8} \quad 9\,.\,.\,10\text{—}11\text{—}$$

With these may be compared the two spectra which more nearly resemble those produced by blood than any I have yet seen.

9. Cochineal in alum (pink):—

$$3\tfrac{7}{8}\overset{*}{\text{—}}4\tfrac{1}{2}\ldots5\tfrac{1}{8}\overset{*}{\text{--}}6\tfrac{1}{8}\ldots7\tfrac{1}{2}$$

10. Alkanet root in alum (pink):—

$$3\tfrac{1}{2}\overset{*}{\text{—}}4\tfrac{3}{8} \quad 5\tfrac{1}{4}\overset{*}{\ldots}5\tfrac{3}{4}$$

The following spectra of compounds derived from chlorophyll are as complicated as any I have met with.

11. Normal chlorophyll in alcohol (deep green):—

$$\tfrac{7}{8}\overset{*}{\text{—}}2\tfrac{3}{8}\text{--}\overset{|}{3\tfrac{1}{4}}\ldots4\tfrac{1}{2} \quad 6\tfrac{3}{4}\,.\,\text{--}\,7\tfrac{1}{2}\text{—}$$

12. Ditto, as decomposed by acids, or as found in some leaves (olive green):—

$$1\overset{*}{\text{—}}2\tfrac{1}{8} \quad 2\tfrac{3}{4}\overset{*}{\text{—}}3\tfrac{3}{8} \quad 4\tfrac{1}{4}\ldots5\tfrac{1}{4}\overset{*}{\text{—}}5\tfrac{3}{4}\ldots6\tfrac{5}{8}\overset{*}{\text{--}}7\tfrac{3}{8} \quad 8\tfrac{1}{2}\,.\,\text{--}\,9\tfrac{1}{2}\text{—}$$

13. Ditto, as decomposed by caustic potash, and then by hydrochloric acid (red-green, neutral tint):—

$$\tfrac{1}{4}\overset{*}{\text{—}}\tfrac{3}{4} \quad 1\tfrac{1}{8}\overset{*}{\text{—}}1\tfrac{3}{8} \quad 1\tfrac{7}{8}\overset{*}{\text{—}}2\tfrac{1}{8} \quad 4\tfrac{1}{2}\overset{*}{\text{--}}5\tfrac{1}{4}\ldots9\text{--}10\text{—}$$

These instruments and methods were exhibited and explained by Mr. Sorby and Mr. Browning at the last *soirée* of the Royal Society, where they excited the greatest interest.

PHARMACY, TOXICOLOGY, &c.

On Colchicia, by John M. Maisch.*

The collection of chemicals in the Philadelphia College of Pharmacy contains a specimen of colchicia prepared by Mr. Carter in 1857; a portion of this was used for the purpose of clearing up the contradictions in the statements of different authors. The substance is a light yellow amorphous powder, possessing a very faint odour and intensely bitter taste, sparingly soluble in ether, but easily soluble in water and alcohol, the aqueous solution being slightly turbid, most likely in consequence of the decomposition of a small portion into resin and colchicein. Heated upon platinum foil, it fuses; at a higher heat, it takes fire and burns without leaving any residue. Placed upon moistened red litmus paper, the blue colour is restored; very faintly reddened litmus becomes blue also by a concentrated aqueous solution. One drop of dilute sulphuric acid dropped from a bottle giving fifty-two drops to the fluid drachm, consequently about one-eighth of a grain HO,SO_3, when mixed with one grain of colchicia, retained its acid reaction. One drop of the acid was mixed with one fluid ounce of distilled water; in five minims of this mixture, equal to about one-seven hundred and seventieth grain HO,SO_3, one-sixteenth grain colchicia was dissolved, and the solution now had a distinct alkaline reaction on slightly reddened litmus paper; but on heating this solution to the boiling point, it had acquired an acid reaction.

The most important tests for recognising the presence of colchicia are its behaviour to dilute acids and also alkalies, by which its solution acquires a yellow colour, and the violet and blue colour which is produced by oxidising agents with dry colchicia. This latter coloration, which changes through various shades finally into yellow, is strikingly beautiful when concentrated sulphuric acid is used, and immediately some

---

* Abstract of a paper in the *American Journal of Pharmacy*, xxxix. 97.

nitric acid or a fragment of a nitrate is added; strong nitric acid produces it likewise, but it changes more rapidly to yellow. Sulphuric acid, with a trace of chromate or bichromate of potassa, or of sesquichloride of iron, or of binoxide of lead, shows the same reaction at the point of contact with colchicia; the liquid itself has a green colour with the first two reagents, owing to their intense yellow colour.

One grain of colchicia was dissolved in one fluid ounce of distilled water, slightly acidulated with muriatic acid; by repeated trials it required 114 drops from this phial to make one fluid drachm; this measure had been carefully gauged with a pipette graduated into $\frac{1}{100}$ c.c. In making the following experiments, a sufficient amount of the reagent was added to enough distilled water to make one fluid ounce, and the solution of colchicia was carefully dropped in until, after stirring, a permanent turbidity was observable. Under these circumstances, it was required of

Mayer's iodohydrargyrate of potassium, 15 drops; turbidity quite distinct.
Sonnenschein's phosphomolybdic acid, 20 drops; turbidity distinct.
Tannic acid, 100 drops: turbidity scarcely observable.

It follows from this that the following amounts of colchicia may be detected by

Mayer's test.......	·01645	grains, or 1 part in	27700	water.*
Sonnenschein's test	·02193	" "	20778	"
Tannic acid........	·10965	" "	4156	"

Solutions of colchicia in water acidulated with sulphuric and with muriatic acid were evaporated and three times taken up by water and again evaporated; the aqueous solutions were finally filtered from the separated resin, and the filtrate slowly evaporated with an excess of carbonate of lead, the residue then treated with strong alcohol and slowly evaporated. Colchicein was obtained in yellowish crystals, which were free from acid and lead. Dissolved in water it still yields precipitates with tannin, phosphomolybdic acid, and iodohydrargyrate of potassium; but neither in solution nor in substance does it produce any reaction on red or blue litmus paper. Rendered faintly alkaline by ammonia, the solution occasions precipitates with the soluble salts of barium, calcium, and lead, which are soluble in dilute nitric acid. Towards acids it behaves similarly to colchicia.

The resinous matter remaining on the filter when colchicein is filtered off was dissolved in alcohol, and the solution evaporated; an amorphous brown-greenish mass was left, in which alcoholic solution has a decided acid reaction. Concentrated nitric acid dissolves it with an evanescent yellow colour; on the addition of sulphuric acid the solution takes place with a purplish brown, rapidly disappearing; pure sulphuric acid dissolves it with a brown colour.

Having looked in vain in every portion of the decomposed colchicia for glucose, or a compound which would reduce an alkaline solution of copper, the observations of Oberlin, Ludwig, and Hübler are confirmed.

Taking all these results together, no doubt colchicia must be looked upon as an alkaloid, the salts of which are soluble in water, but decomposed, with the formation of colchicein, on keeping them in solution as well as on evaporating them. The crystalline mass, obtained by Mr. Carter on evaporating sulphate of colchicia, was undoubtedly colchicein.

Aschoff and Bley observed already that colchicia combines with bases, and that when it is evaporated with a solution of the carbonate of an alkali, the residue contains no carbonic acid. Hübler makes it probable that colchicein is formed under these circumstances. Colchicia is a very weak base, and colchicein, if it can be regarded as an acid, is certainly a weak one, and resembles the alkaloids in its behaviour to some reagents. If colchicia and colchicein have the same composition, the acid resin formed together with the latter can scarcely be different.

In preparing colchicia the action of alkalies and acids, particularly when heat is applied, must be avoided.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, May 1, 1867.

I am now enabled to send you a list of prizes to be awarded by the Society of Encouragement, Paris, and their dates. The aim of the Society is the close alliance between practice and theory. It represents invention, improvement, and application. Every new discovery or invention to ameliorate the state of our national industry emanates from this Society. It makes no distinction between the high-placed theorist and the practical man; those who work in a laboratory, in the study of a *savant*, in a workshop, or as labourers, all are equally welcome and of the same grade. The value of the prizes exceeds 6000*l.* The Society does not confine itself, in their distribution, to industrial matters; it extends its recompenses to individuals. Foremen, workmen in manufacture and agriculture, inventors, pupils of industrial schools, persons invalided by work of hand or brain, receive encouragement, recompenses, and *substantial* aid.

Grand Medals.—Gold medals of 40*l.* to French or foreign inventors who have made the most important discoveries applicable to French industry, to be distributed annually in the following order:—1867, Commerce, bearing the profile of Chaptal; 1868, Fine Arts, that of Jean Gougon; 1869, Mechanical Arts, Prony; 1870, Chemical Arts, Lavoisier; 1871, Agriculture, Thénard; Economical and Physical Arts, Ampère.

Grand Prize of 480*l.*—This is given by the Society to the author of a discovery deemed to be the most useful to French industry.

Prize given by the Marquis Argenteuil.—The same amount as the last, awarded to the discoverer of a special invention or improvement, principally with regard to objects in France which have not been yet able to compete with foreign markets, either as to quality or cheapness.

Prizes for 1868, 1869, 1870, 1871, 1872, 1873, *and* 1874.

Mechanical Arts.—Prize of 120*l.* for the best machines for steam navigation, which, with slight draught of water, can enable the machinery and coaling room to be diminished, and thus increase the available space; 1869.

Prize of 120*l.* for a locomotive able to take a goods-train at the rate of thirteen to eighteen miles an hour, with a minimum of expense of prime cost and combustion of fuel; 1870.

Prize of 240*l.*, for a motor engine, from 25 to 100-horse power, burning at the most $1\frac{1}{4}$ lbs. of coal of best quality per indicated horse-power, weighing less than 661 lbs., and costing from 12*l.* to 16*l.* per horse-power; 1871.

Prize of 40*l.*, founded by the Princess Galatzin, for a hydraulic motor for a small workshop, able to work a shaft representing a force of 6 to 20 kilogrammetres* per second; 1868.

---

* One fluid-ounce water = 455·669 grains.

*A kilogrammetre is a kilogramme (2·205 lb.) raised to the height of a metre in one second.

Prize of 160*l.* for improvements to be effected in the mechanical weaving of linen and hempen goods; to be awarded in 1872, in favour of the manufacturer who can produce commercially linen threads of a fineness of 100 metres to the gramme, or hemp threads 15 metres. This must be obtained by an economy of at least 15 per cent. of the motive power, and with such a diminution of temperature that there is little or no steam. The manufacturer must have delivered to commerce at least the value of 800*l.* worth of threads of linen or hemp, according to the above stated conditions.

Prize of 120*l.* for a file-making machine able to cut all sorts; 1870.

Prize for a practical and economical means of cutting millstones, whilst diminishing the insalubrity of this branch of industry; 1869, or, if necessary, 1875.

Prize of 80*l.* for a water-meter, acting under a pressure of from 1 to 5 atmospheres with a temperature of 0° to 100° C., and giving the volume of water to within a hundredth part; 1870.

Prize of 40*l.* for a regulator for gas burners.

Chemical Arts.—Prize of 80*l.* for the best process of making oxygen on a large scale; 1869.

Prize of 120*l.* for the industrial application of oxygenated water.

Prize of 80*l.* for extracting the nitrogen of the air in the form of nitric acid or ammonia; 1869.

Prize of 80*l.* for the economical production of cyanide by the nitrogen of the air; 1871.

Prize of 120*l.* to be awarded (1870) to the manufacturer who shall be the first to produce sulphuric acid, quite free from arsenic, from pyrites.

Prize of 40*l.* for the industrial employment of any cheap and abundant mineral; 1868.

Prize of 40*l* for the utilisation of the refuse of factories; 1869.

Prize of 40*l.* for the useful application of the newly-discovered metals; 1870.

Prize of 40*l.* for new applications of simple substances, non-metallic; 1870.

Prize of 40*l.* for the discovery of a new alloy useful in the arts; 1871.

Prize of 120*l.* for the artificial production of graphite for the fabrication of pencils; 1872.

Prize of 120*l.* for the artificial preparation of the compact black diamond; 1873.

Prize of 160*l.* for the discovery of processes capable of furnishing, by any organic transformations, useful substances, such as quinine, indigo, alizarine, or cane sugar.

Prize of 160*l.* for the artificial production of fatty acids and of waxy substances.

Prize of 240*l.* for a theory of cast-steel founded on certain experiments; 1872.

Prize of 120*l.* for the disinfection of the refuse from the purifying of gas; 1869.

Prize of 40*l.* for a process capable of disinfecting and clarifying, quickly and durably, sewage water; 1868.

Prize of 60*l.* for the discovery of an ink which will not rust metallic pens; 1869.

Prize of 120*l.*, 60*l.*, and 20*l.*, for the employment of boracic acid and borax in the ceramic arts; 1868.

F. MOIGNO.

PARIS, May, 8, 1867.

THE learned societies of the Scientific Association of France held their annual public meeting at the Sorbonne, Wednesday, Thursday, and Friday of Easter week. The meetings were not well attended, and the few subjects discussed were not very interesting; the attraction of the Exhibition threw them into the negative pole of sight-seeing or lecturing. The distribution of the prizes took place on Saturday, April 28, at noon. M. Blanchard, Professor of Natural History at the Museum of Natural History, and member of the Academy of Sciences, gave a good summary of the scientific works carried on in 1866–1867. His good nature and lively imagination were actually necessary to conceal or counteract a truly lamentable sterility of subjects. We must say, notwithstanding the rather timid protestation of the Minister of Public Instruction, that the sciences, mathematics, physics, geology, botany, and meteorology have lost in France much of their ground; our mathematicians, physicists, and naturalists have let themselves be outstripped by foreign *savants* on the field of pure science. The Prussian needle-gun and the Enfield rifle have taken the palm out of our hands; they have, we may say, silenced the fire of our rifles.

This is a sad statement, but, alas! too true. The Congress that we have above mentioned was only a gloomy shadow compared with a meeting of the British Association for the Advancement of Science.

Apropos of the ozone-generating machine experimented upon by Mr. Beanes at the last *soirée* of the Royal Society of London, let us humbly call to mind that we were the first to make known the nature and application of this mysterious agent. In 1845, on the first news of the curious observations of M. Schönbein, we proceeded to Basle, and visited the celebrated chemist and professor. He condescended to repeat before us his numerous experiments, and we wrote to the *Epoque* a letter inserted on Dec. 31. The following very important passage occurs: "It is necessary to return immediately to the ideas of Ampère, and consider the atoms of bodies as having two states—first, with the essential primitive electricity or in a nascent state; second, with their electricity more or less disseminated, or their atmosphere of electricity in a neutral state. The ozone of M. Schönbein is, in our eyes, only a molecule of oxygen in a nascent state, with only negative electricity in its atmosphere. I am, I think, able to rigorously prove and account for the wonderful properties of this agent that we cannot lay hold of, and of which so much has been said." We ask all the chemists in general of that time, and Dr. Thomas Andrews, of Belfast, in particular, whether at that period any one had so clearly defined the essential nature of ozone, so much talked about, written upon, and discussed without coming to a decided conclusion.

Two years afterwards, when uncertainty yet reigned in all minds, we inserted in the *Nouvelle Revue Encyclopédique* of M. Didot, in the number for July, 1847, the following more explicit lines: "Sufficient attention has not been yet paid to the important fact that oxygen disengaged by plants is not in a neutral state. We are perfectly convinced that this nascent oxygen, without its positive atmosphere, is the ozone discovered by M. Schönbein, with an odour *sui generis*, and possessing, in the highest degree, all the properties of electro-negative substances. The bleaching of linen stuffs, ivory, wax, &c., in the open air, on grass, the formation of nitric acid and saltpetre, also many other phenomena, are only caused by the powerful action of oxygen in a nascent state, or with its negative electricity developed." From 1845 to 1867, thousands of contradictory opinions have been written on the subject of ozone, to return again to the idea that we so clearly pointed out. We have so often pleaded the cause and defended the interests of others, that we must be pardoned for establishing, once for all, and very humbly, our own claims.

The Society for the Encouragement of National Industry has decided that, during the whole time of the Exhibition, it will hold weekly meetings, not on Wednesdays, as on that day too many members of the Council will be elsewhere engaged, but on Friday, when one is in general more free from domestic or social engagements. The first of these meetings took place on May 3, under the presidency of M. Dumas, and the aspect of the hall, the tables covered with crystal and glass, gas-burners, objects in aluminium, &c., show at once a successful departure from the habits of the Society. The correspondence was, as usual, opened by the two secretaries, but it contained nothing interesting. M. Tessié de Mothay, in his name and that of M. Maréchal, of Metz, read a description of the processes of phototype which have led them to the definitive solution of the great problem of the indefinite reproduction, with thick and indelible inks, of photographic images. M. Tessié regarded as antiquated the anterior essays with regard to M. Davanne, of whom we have already spoken. He need not then speak of the photographic processes of MM. Nièpce de St. Victor, Lerebours, Lemercier, and Barreswill, long since practised by the eminent photographer, M. Lemercier. Meanwhile, M. Barreswill thought proper to call to mind this first solution, and even thought that he was able to add that he had given results almost identical with those of the new process. We venture to affirm the contrary, and we are sure we shall not be contradicted on this point by M. Lemercier, who is very glad to substitute the new process for his own, the success of which was uncertain. The employment of so large a quantity of ether rendered difficult and unhealthy the process, which had already given way to the incomplete method of M. Poitevin.

M. Dumas then gave the *parole* to M. Paul Bérard, who directs, with M. Paul Audouin, the Laboratory of Essay for the Illuminating Power of Gas, established in the Rue du Faubourg Poissonnière for the Municipal Administration of Paris, under the head direction of MM. Dumas and Regnault. The young chemist resumed, and confirmed by many experiments results obtained, having a double view—1. Two flames of equal density being given, one produced by a carcel lamp burning under fixed conditions, the other by a gas burner, burning as much as possible under the same conditions, to determine the respective consumptions of oil and gas, in a given time, for each of the apparatus; 2. To study different burners, and the best conditions for the combustion of the gas.

The first problem was completely resolved by a series of photometric apparatus, very well constructed by M. Deleuil, and which comprise a carcel lamp burning at the normal rate of oil, a Foucault photometer with starched glass plates, and a telescope and movable plates, a standard burner and an argand one with 30 holes, and an automatic balance indicating by a scale, with the precision of 1 centigr., for a charge of 3 kilos., the quantity burned by a carcel lamp. M. Audouin said nothing of the photometric method; he did not even mention the name of M. Deleuil, but he enumerated very rapidly the conclusions of the experiments on burners. Let us mention them, as they are truly well defined. With *bat's-wing burners* the maximum of illuminating powder corresponds to a slit $\frac{7}{10}$ths of a millimetre wide. The same quantity of gas can give, when it burns in a good burner, four times the light given by a bad one. The increase of illuminating power corresponds to a very rapid diminution of pressure, and consequently to the diminution of the velocity of flow; in other terms, with equal consumption of gas of a constant composition, the greatest illuminating power corresponds to the lowest pressures, the maximum corresponding to a pressure of 2 to 3 millimetres. The proportion between the diameter of the nipple and the expenditure, keeping the same width of slit, $\frac{7}{10}$ths of a millimetre, has next to be determined. The gas flows with the same velocity or under the same given pressure, always with the same illuminating power, whatever be the bat's-wing in which it burns. For very different intensities the dimensions of the flame vary very little, its height being sensibly constant and terminated by a right line. *Other burners than bat's-wings.* Bougie burner, a nipple with a hole in the centre. For the same height of flame, the illuminating power always coincides with weak pressures and a hole of $\frac{7}{10}$ths of a millimetre; it increases almost indefinitely with the height. The great expenditures of gas are more advantageous than the weak ones. Manchester burner, a nipple pierced with two holes. When the diameters of the holes are very small, two bougie burners give a light equal to that of a Manchester burner, which they can form by their union. But the superiority of the Manchester burner over the two bougie burners becomes more and more considerable according as the holes increase in diameter. The maximum lighting power corresponds always to the minimum pressure, and to a diameter of $\frac{7}{10}$ths of a millimetre. *Burners with a double current of air.* The argand burner of 30 holes, $\frac{7}{10}$ths of a millimetre, proved the most advantageous of all, and it is much to be regretted that it was not compared with the Monier burner, which is much more economical again. The lighting power increases indefinitely with the expenditure; the height of the chimney should not exceed 20 centimetres. The quantity of air burned by a burner is not proportional to the consumption of gas; all the burners do not require the same amount of air in order to give the maximum of lighting power. The introduction into common gas of 6 or 7 per cent. of air diminishes its lighting power by a half. 20 parts of air mixed with 30 parts of gas gives no light.

The standard carcel lamp consumes 42 grammes of oil per hour. According to the treaty between the town of Paris and the General Gas Company, 25 litres or 27½ litres of gas burned in a standard burner under a pressure of two or three millimetres, should furnish a flame equal in intensity to that of a carcel lamp burning during the same time 10 grammes of purified colza oil.

M. Debray then resumed the history of the preparation, properties, and uses of aluminium discovered by M. Wöhler, and brought into use by M. Henri Sainte-Claire Deville. The principal progresses made in this industry are—Utilization of bauxite, a clay very common in the south of France, composed nearly exclusively of alumina and sesquioxide of iron; to this is due the purity of the aluminium of commerce. The employment as flux of salt and cryolite (double fluorine of aluminium and sodium, very abundant in Greenland). This metal is used for optical instruments, and many other objects of jewellery, &c., and even for culinary purposes. Aluminium bronze, composed of copper 90 to 95, aluminium 5 to 10, is its principal use. M. Debray stated as extraordinary facts that this bronze, containing 95 per cent. of copper, was very little attacked by acids; also that chlorine was a deleterious gas, and sodium poisonous, but that chloride of sodium (table salt) was innocuous!

When M. Debray sat down, M. Dumas rose and indicated in a few words the aim of these weekly meetings. What characterises, he said, the Exhibition of 1867 is the enormous progress made in the application of the sciences to industry and fine arts; everywhere in these immense galleries we see the facts and theories of pure science become materialised into practical applications of great value. Is it not very natural, then, that the Society of Encouragement should become the revealer and appreciator of the successes obtained in what may be called its special department?

We are surprised that the illustrious President does not try some other thing than a reduced copy of our own programme in the conferences of the Exhibition of 1867. He attempts to perform far from the galleries, in a very confined space, in presence of a very limited auditory, what we aspire to do in the midst of the Champ de Mars, in a great amphitheatre holding 500 auditors. How does it happen that the Commission of three members, the triumvirate, Dumas, Michel Chevalier, and Perdonnet, charged by the Imperial Commission with its organisation and direction, have not signified to us, by the intermediation of M. Perdonnet, their intentions issued as follows?—1. That the entries shall be gratuitous. 2. That none of the lectures shall be paid. 3. That no exhibitor shall be admitted, either by himself or by a third party, to exhibit or make known the progress he has accomplished. Is it not tyrannically unjust to make gratuitous a lecture-hall, constructed according to a very severe specification, entailing an expense of 50,000 to 60,000 fr.? Is it not barbarous to prevent 100 or 200 francs from being taken from the money received at the doors and given to the *savant* who may have succeeded in interesting a vast auditory, and initiated them agreeably and usefully into the nature and advantages of some novel branch of industry? St. Paul characterised this barbarism in remarkable terms in his Epistle to the Corinthians, when he told us not to muzzle the ox while eating.

Lastly, it is astounding that what is permitted, honourably, legally, and praiseworthily, under the patronage of the illustrious President of the Council of the Society of Encouragement, could at once become illicit and blamable in the eyes of the Imperial Commission, of which he forms part, even of the *triumvirate*. The letter of M. Perdonnet we keep with great care. The triumvirate is totally ignorant of the fact that the lecture-hall was mounted (it is very nearly finished) at private expense, on the same terms as the other establishments of the Champ de Mars Park. A lecture-hall on the subjects of objects exhibited seems to us an indispensable adjunct; yet the Commission did not think it worth their while to build one; they gave the concession of ground to the celebrated photographer, M. Pierre Petit (who had already given £2800 for the site for his pagoda), on condition that he would build a lecture-hall and furnish lectures, the profits of course to be his own. Not so. Right about face with the Commission. The lecture-hall being done, and the expense paid for, M. Petit is told that all his labor in that direction is in vain. The Commission should, at least, reimburse the sum he laid out in bricks and mortar to please the Imperial Commission. Do they want to rob him also? Every establishment for public amusement is there opened on the adjoining grounds, and they place *what price they like* for entrance; but intellectual and practical information, the food of the mind, seems to find no favour with the triumvirate. F. Moigno.

Paris, May 15, 1867.

The Academy of Sciences includes in its body four sorts of members—titular, foreign associates, free academicians, and correspondents. According to the spirit which animated its creation under the ancient monarchy, the free academicians were ordinarily high-placed men, or at least men occupying an elevated position in society, well known to be the friends of science and disposed to patronise it. They had all the rights and privileges of titular academicians—that is to say, they took part in all the elections, could form part of all the administrative or other commissions, &c. They did not receive the small stipend attached to the rank of member of the Academy, but they took their share of the presentation tickets. In this primitive state of things, the title of free academician was superior to that of the titular one, and it was ridiculous to ask the first-named to abdicate in favour of the latter. At the time of the re-organisation of the Institute of France and of the five academies which compose it, the democratic spirit which predominated at the discussion of the regulations—at least as far as concerned the Academy of Sciences—ended by putting the primitive and very legitimate institution of the free academicians in a false position, and in reducing their body to an inferior number, and thus subjecting them to humiliation, though they were always chosen from the first ranks. For example, they are deprived of their votes in the elections of titular and corresponding members, and they cannot take part in any elections except for free members like themselves. In our opinion this inferiority, contradictory in itself, ought to have disappeared long ago, the more so as it keeps up in the Academy an antagonism much to be regretted, and a mutual silent but deep-seated discontent, which has already given rise to violent discussions, and, we are sorry to say, combats with arms less noble and worthy of the members. At this moment the fire is smouldering under their feet, and may burst out as a volcano. Among the ten free academicians, three—Marshal Vaillant, M. Antoine Pussy, Count Jaubert—are present or former Ministers of State. The most ardent advocate in defence of the rights of the corporation is the Count Jaubert, well backed by the most ancient of his colleagues, Baron Sequier, a distinguished amateur mechanical engineer, formerly councillor at the Royal Court of Paris. Marshal Vaillant does not take any visible part in the conflict, but he nevertheless is mixed up in it, perhaps with a sort of disgust at the proscription with which the free academicians are struck, and he hopes, openly, but timidly, to push into the list of the titulars. A most distinguished officer of the French military engineers, universally informed, an ingenious and popular writer, an eminent agriculturist and meteorologist, he had, in the judgment of François Arago, and, we may say, of everybody else, all the talents and qualities for a titular academician; no one could be more fitted to fill a chair actively. It was a good occasion for granting his request. Not without his high influence the Academy entered into possession of their new chair; if the Marshal had not objected, the Emperor would have, according to the accustomed usage, named by decree the first titulars, and in the first place Marshal Vaillant. In how many circumstances the Marshal has been the ready and powerful intermediary between the Academy and the executive for the foundation of new prizes, the increase of the value of existing ones, or the concession of scientific missions! He has been advised to resign his position as a free academician, and to be proposed as candidate for the place of titular academican in the section corresponding to his works. He will not do that; he cannot, on account of the respect for those who share the seat with him—a seat awkwardly lessened not in dignity but in rights. He declares that he puts himself solely at the disposal of the Academy, and that, although he will not resign his present chair, he will accept with gratitude the chair of titular academician.

What is wanted more? Can we understand how a body formed of such celebrated scientific men can much longer hesitate in acquitting what we do not fear to call a debt of honour and gratitude? Marshall Vaillant had two votes in the last election, and we have heard them named as unconstitutional. This is a farce, and these two votes must absolutely become unanimity for the election of the Marshal in the Section of Geography and Navigation. Thus, if the Academy of Sciences does not decide upon rendering to the free academicians their primitive rights of participation in all the elections, it ought at least to suppress the derisive term; for it is repugnant to common sense now to have only the mutilated honour of a free academician.

We have not succeeded in ascertaining at all definitely the series of the deliberations and the awards of the juries. We know, however, that in Class 72, Group VII—sugars and confectionary products—the jury propose to award four gold medals: the first to Prussia, the Zollverein exhibitors, for the *ensemble* of their products, and especially the sugars manufactured directly and ready for immediate delivery for consumption; the second to the Mauritius for the considerable increase in the production and the progress accomplished; the third to M. C. A. Say for the products of his refinery, an excellence demonstrated by the enormous quantity and the extent of his exhibition; the fourth goes to France, considered in the light of its being the mother country of the great industry of sugars. Here, again, the needle-gun carries off the palm, and we are well beaten.

The Society of Encouragement held on Friday, the 10th inst., their second extraordinary meeting. The correspondence, summed up by MM. Tresca and Peligot, presented nothing of any interest.

M. Huzard read, in the name of M. Bells, a very favourable report on the shearing machine of M. de Nabat. For clipping horses and sheep-shearing it has been most successful. We prefer by far the little shearer of M. Cazon, which is held and set in motion by the hand, whilst that of M. Nabat is a real machine, like a knife-grinding one, set in motion by the foot.

M. Dumas read a letter, by which our friend, M. Galibert, in gratitude for the success of his respiratory apparatus, placed at the disposal of the Society of Encouragement the sum of 1,000 fr., to be employed in forming a fund for the prize, for the best application of the endosmose of gases, to be awarded in 1868. This is one of the questions put forward in the programme of prizes which are most in relation with Galibert's apparatus. M. Dumas congratulated M. Galibert on his generosity, and tendered him the thanks of the Council.

M. Dumas read a second letter from M. Taborin, one of the oldest manufacturers of files, who, spontaneously on his part, and in thankfulness for his success, took upon himself to hand over 3000 fr. towards the prize to be awarded in 1868 for a file-cutting machine. This mark of gratitude to the Society was most warmly applauded, and the noble veteran, much affected, rising to give thanks to M. Dumas and the Council, to the great surprise of the auditory, said: "To cut files is hard work, and the Society has done well to appeal to mechanical skill for alleviating it; but the forging of them is worse again, and I beg the Society instantly to found, at my expense, a second prize of 3000 francs for a machine for forging files." Much moved, in his turn, M. Dumas exclaimed, "Honour to the intelligent and energetic man who commenced his industrial career forty years ago with only two and a half francs in his pocket, who has now founded three vast establishments, and who has arrived at a trade of several million francs with honour and profit."

M. Balard presented, in the name of M. Carré, his new ice-producing machine, of which we have often spoken and given a description in our report of the Academy. The principle of this machine consists of sulphuric acid marking 59° to 66°, circulating in a thin stream, through which passes vapour of water drawn along by a vacuum created pneumatically. The evaporation of this produces the cold. The recipient of the acid is formed of an alloy of lead and antimony in the proportion of 5 to 6 per cent.; it supports, without alteration of form, a pressure of five or six atmospheres, while the pressure in practice cannot exceed one atmosphere. The copper pump is preserved from the contact of the sulphurous acid, always disengaged by the acid recently introduced, by an arrangement which necessarily and constantly oils the inside surface. The valves are opened mechanically, and cannot get deranged. The apparatus keeps the vacuum for several months; the acid is extracted when it has become diluted to about 52°; the congelation commences generally three or four minutes after the commencement of making the vacuum; if cold water at 3° or 4° C. is required, two minutes suffice, and a little shaking up for some instants restores the air which it has lost. Other substances can be substituted for sulphuric acid (which is, however, the cheapest agent to employ), such as caustic potash or soda, or chloride of calcium, which cause a congelation sufficiently prompt and intense. In the application, M. Carré mentioned the adaptation of the apparatus on board ships and in cellars where the temperature could be indefinitely kept at 5° or 6° C. in all latitudes, also for the refrigeration of apartments.

M. Dumas is of the same opinion as M. Balard, with regard to the success of the new ice-making machine, especially if sulphuric acid can be replaced by other substances more inoffensive; he indicated that oven-dried bran, a powerful absorbent, might be tried, and requested M. Thénard to give his opinion, and to state what advantage agriculture would derive from this mode of producing cold. M. Thénard first called attention to the curious and important fact discovered by milk-women, and of which he cannot find an explanation. If milk, a few minutes after being drawn from the cow, be cooled with very cold rain-water, it keeps fresh for many days, and can be sent to a long distance. Carré's apparatus can advantageously replace the cold water, especially in agricultural distilleries, which employ a good deal of sulphuric acid and keep at the same time a great number of cows.

M. Peligot afterwards gave an account of the process of M. Paris for the fabrication of enamels, of which numerous beautiful specimens were laid before the Society. We will resume this subject further on while speaking of the Exhibition.

M. Peligot also called attention to a quite new fact that he had discovered. It arose from the devitrification of a piece of St. Gobain glass, prepared a long time ago by M. Pelouze; the glass had lost its transparency, but not its density. Placed in a drawer, the piece of glass, supported by one extremity, was found, after some days, by M. Peligot, to be curved under its own weight, it having become a malleable glass; the surface was also covered with efflorescence. Pliny speaks, in his history, of a glass that could be bent and unbent; and the story goes that Richelieu ordered an inventor to be put to death for proposing to divulge a process for making malleable glass.

M. Bouillet, in his name and that of the celebrated M. Christofle, mentions two great improvements made in their electro-metallic manufacture. 1. Round bossed galvanoplastic objects could be obtained more economically by the substitution of electrodes of lead for the insoluble platinum wire electrodes used at first by M. Lenoir, the inventor of the process. 2. A series of pieces in bronze, decorated with inlaid work in silver, platinum, and yellow or green gold, had been obtained by electricity, and which perfectly imitated the charming objects coming from China or Japan.

F. Moigno.

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Group VI.—Class 44: Chemical and Pharmaceutical Products—Industry of Colouring Matters extracted from Coal.

This great industrial art, illustrated for the first time at the International Exhibition of 1862 with great *éclat*, has not ceased to develope itself, less, however, in France than in Switzerland and Germany, where the progress has been considerable. With us progress was fettered by the fact that aniline red, the basis of all the other colours, was the exclusive property of the Fuchsine Company, and was, in consequence, a general monopoly. The great problem under these conditions was to arrive by direct process at violet, blue, and green colours without passing through the red; it has at length been resolved for violet by MM. Poirrier and Chappat, jun., of Saint Denis, with the able assistance of their chemist, M. Bardy. The methylaniline and dimethylaniline violets, exhibited under the name of "Paris Violet," are the gems of the chemical section, and have most attracted the attention of practical men, also of the jury, who have awarded them a gold medal.

Before describing this discovery, we may remark that the Fuchsine Company have kept up their reputation, and that the display in their glass case is really magnificent; their sphere of radiating crystals, so sharp and voluminous, of chlorhydrate of rosaniline, along with all the salts of rosaniline, have a wonderful effect. They find a powerful rival, however, in M. Müller, of Basle, who also exhibits a large collection, the principal article being a cup containing a pound of rosaniline so pure that it is almost colourless. We have not found chrysotoluidine or malvaudine except on stuffs of silk and cotton, of which specimens are exhibited by MM. Hucotte and Berryer, also the blues of MM. Girard and Laire, the process of which shall be described presently.

The Paris violet, by MM. Poirrier and Chappat, No. 23 Rue d'Hauteville, stall No. 2, is produced from the methylaniline and dimethylaniline which Dr. Hofmann discovered and made known by a process very costly and not put into practice. The celebrated chemist employs as a reducing agent the very volatile iodide of methyl, and this would have entailed a considerable loss if 800*l.* per day were constantly risked—that being the quantity necessary to produce 150 kilogrammes of methylaniline that MM. Poirrier and Chappat send to the market every day. In order to arrive at a remunerative product, they have substituted a cheaper substance, nitrate of methyl, for the iodide; it is by this means that they were able to produce their first *ton* of Paris violet at their chemical works. Still this mode of fabrication was fraught with danger, and was discontinued. Happily, M. Berthelot pointed out a process less dangerous and cheaper, the treatment of ammonia by alcoholic radicals.

To obtain methylaniline or dimethylaniline, MM. Poirrier and Chappat place in contact in a closed vessel, at a high temperature, and under pressure, aniline and hydrochlorate of aniline, or methylaniline and hydrochlorate of aniline; and this process, which has required the construction of special apparatus, the application of means for regulating the reaction in order to obtain at will either methylaniline or dimethylaniline, &c., works at present with perfect regularity; they have extended, with success, the process towards the preparation of other alkaloids based on an alchoholic radical. There remained yet the means of converting methylaniline and dimethylaniline into violet, soluble in water, as there is no complete success without this condition. New agents had to be searched for, that do not require a too high temperature, in order to produce the reduction, or the return would not be so great, nor the colour so bright or of so decided a shade. They finished by transforming the perfectly pure methylaniline from toluidine into violets of all shades not inferior to those derived from the rosaniline of Hofmann.

MM. Tessié de Mothay and Maréchal, of Metz, exhibit a new process for bleaching fibres, threads, and woven stuffs of cotton, hemp, linen, wool, and silk.

The fibres, threads, and tissues contain two sorts of colouring matters—one soluble, after oxidation in alkaline lixivia; the other substances inherent to the cellulose, which should be bleached by the oxygen of the air and light, or by chemical compounds able to disengage oxygen in its nascent state.

The methods hitherto employed for bleaching or decolorising tissues depend upon the alternate application of two sorts of agents—1. Oxidising substances; 2. Solvents.

But these methods, perfect as they are in their way, have the following faults:—The employment of an oxidising agent which acts with extreme slowness when it is taken from the atmosphere, or with a destructive combustible power when it is several times placed in a medium containing chlorine or the chlorated compounds, such as the hypochlorites, for example: the use of alkaline solvents which act with extreme slowness in dissolving the quantity of colouring matter altered by the oxidising agents. For these latter the most suitable substitutes are—1. Permanganic acid, produced by the decompositition of the permanganates by means of hydrofluosilicic acid. 2. The alkaline permanganates, with the addition of chlorides, sulphates, and alkaline fluosilicates capable of forming salts, having for base permanganic acid, at the moment when this acid is decomposed by the fibres; passing, themselves, into a basic state, as is shown presently.

In order to employ practically the oxidising agents and solvents above mentioned, the operation is thus:—

For bleaching stuffs or threads of cotton, linen, or hemp, all the grease or fatty matter is extracted by an alkaline bath. They are then steeped in a solution of permanganic acid or permanganate of soda, with the addition of sulphate of magnesia. Afterwards (fifteen minutes' interval generally) the substances to be bleached are removed and transported either into alkaline solutions or into baths containing sulphurous acid, nitrosulphuric acid, or peroxide of hydrogen.

In the first case the substances are heated to boiling-point in alkaline solutions for several hours until the oxide of magnesia which covers them is partially or wholly dissolved.

In the second case the substances to be bleached are steeped in baths containing either sulphurous acid or nitrosulphuric acid or oxygenated water, until the layer of oxide of manganese, with which they are coated, is entirely dissolved; after this they are washed and resteeped, first in a solution of permanganic acid or the permanganate, afterwards in alkaline solutions or in the solvents above mentioned, and so on till the bleaching is completed.

A bleaching-bath, containing, according to the nature of the fibres or tissues to be bleached, from 2 to 6 kilos. of permanganate of soda, is sufficient to bleach effectually a hundred kilos. of cotton, hemp, or flax, raw or woven.

This method of bleaching is the same for wool and silk, except that the alkaline liquid is a weak solution of soap, and sulphurous acid is alone employed.

The industrial results obtained in the factory of M. Verlay, at Comines (Nord), by the above-mentioned process show that hemp and linen threads are completely bleached without alteration in one day; that their tissues are bleached in three days; that the cost for complete bleaching is on an average 3½d. the kilo. for threads, and 5s. per 100 metres for the woven stuffs.

By the present methods of bleaching, even the most rapid and economical, for all textile substances or tissues, threads require, according to the daylight and weather, at least fifteen days and at most thirty; tissues from thirty to sixty days. Also the cost of bleaching, on the other hand, amounts in similar cases to about 4½d. per kilogramme for threads and 7s. 6d. per 100 metres for tissues.

In order to obtain the practical result which we have just mentioned, new economical processes were necessary to be found:—1. The production of manganate of soda; 2. To transform this manganate into permanganate.

Lastly, we mention that manganate of soda is now prepared and sold at the rate of one franc per kilogramme to bleachers.

Its transformation into permanganate is easily and cheaply made, either by means of sulphate of magnesia, chloride of magnesium, or chloride of calcium.

The following formulæ show the transformation:—

$$3(\mathrm{KO,MnO_3}) + 2(\mathrm{MgO,SO_3}) =$$
$$= \mathrm{KOMn_2O_7} + 2(\mathrm{KO,SO_3}) + 2(\mathrm{MgO,HO}).$$

Long ago the researches of Messrs. Deville, Lechatelier, and Kessler proved that fluosilicic acid, if it could be produced cheaply, would most advantageously replace sulphuric acid in the great industries of potash and soda. On the one hand, some facts seem to indicate that, under certain conditions, silica, melted with fluoride of lime at the highest temperature of our furnaces, produces fluoride of silicium and silicate of lime; on the other hand, celebrated German and English engineers affirmed that the furnaces for smelting copper with fluoride of calcium disengaged at the furnace mouth fluoride of silicium, which seems to indicate, conformably with the analyses of M. Berthier, that carbon played a great part in the production of fluoride of silicium by the dry way. Starting from these principles, M. Tessié de Mothay caused to be melted in a closed crucible a mixture of two equivalents of silica, three equivalents of fluoride of calcium, and four equivalents of carbon; and he proved that at the temperature of melting iron a great quantity of fluoride of silicium was evolved. The slag resulting from the calcination, when analysed, showed that the fluoride of calcium had lost 52 per cent. of its fluorine; and direct observation proved that the fluoride of silicium produced was always accompanied by carbonic oxide gas. Convinced by these preliminary experiments of the possibility of the industrial production of fluoride of silicium, M. Tessié de Mothay made, along with M. Ede Kescher, of Sarrebruch, in a melting-pot of the works at Ars-sur-Moselle, a first essay at reduction. This was crowned with complete success, and they proceeded immediately to construct furnaces for the production on a great scale—first, of fluoride of silicium and fluosilicic acid; second, of caustic potash and carbonate of potash, extracted by the action of fluosilicic acid from the chloride of potassium of the Stasfurth mine. The quantity of fluosilicic acid obtained in the blast furnace of Gröbleterstroff, near Sarroquemines, is already sufficient to enable them in some months to deliver a ton of potash per diem at a cheap rate to the trade.

This process of fabrication is very efficacious and simple, since, by aid of fluosilicic acid, they collect 68 per cent. of the fluorine contained in the fluoride of lime. It consists in —1. Kneading, as in a brick-making machine, carbon with a mixture of silex, clay, and fluoride of lime, in quantities proportionately equivalent, and the formation, after fusion in the blast furnace, of a bibasic silicate of alumina and lime. 2. Mixing the cakes with the proportion of coke necessary for the fusion. 3. Filling all the furnaces through a double chamber to hinder the passage of the gases by the furnace mouth. 4. To melt the cakes by an intense heat produced by powerful blowers, and to collect the gases in condensers whose surfaces are continually wetted, so that the immediate contact of the water decomposes the fluoride of silicium into hydro-fluosilicic acid.

In Class 51 is exhibited a complete plan of the works and blast furnaces of Grösbleterstroff; and in Class 44 a series of bottles containing fluosilicic acid of 180°, fluosilicate of potash, of soda, and of barytes, caustic potash, and soda, which the fluosilicic acid has separated from their combinations with sulphuric acid.

Chemists, only a few years ago, would have refused to believe that one could procure so easily and certainly, and on so large a scale, a product hitherto confined to the laboratory, but now destined to modify in the most successful manner one of the most important of modern industries.

Paintings on glass required to be transparent must have a thickness of enamel four or five times greater than that of paintings on ceramic paste, which are to be viewed by reflection. Hence it follows—1. That the designs made to be transferred to glass cannot be printed from ordinarily engraved copper plates, since, after baking, it would not have the necessary thickness and opacity; 2. That the organic matters serving as a vehicle for the vitreous flux to make the impressions must be increased in a quantity proportional to the amount of the enamels they are to contain.

In order to resolve the problem of impression by means of applied drawings of enamelled pictures vitrefiable on glass, it was necessary to have recourse to the employment of deeply engraved plates, similar to those for paper-hangings and stuffs, and organic inks containing the enamels in a state of combination.

But all the vehicles hitherto employed for printing enamels, porcelain, and earthenware, when mixed with colouring fluxes in sufficient proportion to permit of the impression, cause on the glass, during the baking, the deformation of the designs, and, in numerous places, non-adherence to the surfaces they cover. The same effects of deformation and non-adherence are equally produced with inks composed solely of resinous siccatives, essences, bitumens, resins, and other analogous vehicles.

MM. Tessié de Mothay and Maréchal have happily proved that the organic inks favour, on the contrary, the union of the vitreous flux with the sheets of glass; in fact, the solvent of the colouring matters used in painting on glass is in general silicate of potash and lead, or a silico-borate of the same bases. This combination, rendered plastic by the addition of more or less resin dissolved in the turpentine, is a perfect ink, which, printed in a thick layer and transferred to glass, is burnt and vitrefied without deformation or air-bubbles. Thanks to it, it is possible to employ, for the reproduction of ornamental or plain prints, the rollers with deeply cut lines, which serve at Mulhouse for the printing of stuffs. Worked by steam power, these rollers produce in an hour more than 250 skilful designers could do in a day. Many thousands of plain patterns and mosaics of stained glass produced by this process already adorn our churches, and the low price at which they are produced and sold tends every day to multiply the number.

The same investigators have also discovered a new method applicable to the production of photographic images of all sorts on glass, enamel, lava, porcelain, earthenware, &c. It comprehends a series of ten operations, which we will summarily describe in their order:—1. Four parts of caoutchouc are dissolved in a hundred parts of benzol. To this solution is added one part of normal collodion. This compound is poured upon any of the substances on which a vitrefiable portrait is required to be produced. It is then dried, either in the open air or in a stove, until a very coherent coating is formed. 2. On this first coating, thus dried, iodised collodion is poured. This second coating unites intimately with the first, and thus acquires a resistance equal at least to a layer of caoutchouc of the same thickness, a resistance which no ordinary collodion possesses. 3. After having immersed the double coating, thus prepared, in a bath of nitrate of silver, an image is produced on it, either by a camera or by superposition. 4. The latent image thus produced is developed by any of the agents generally used. 5. It is then fixed by successive action of two baths, one containing a solution of an iodocyanide, and the other an alkaline cyanide. 6. The image thus fixed is steeped for some instants in a solution of sulphate of protoxide of iron, pyrogallic acid, or any other substance that will reduce the salts of silver. 7. The image is intensified by the action of pyrogallic acid, gallic acid, formic acid, or sulphate of protoxide of iron, mixed with an acid solution of nitrate of silver. This strengthening requires, on an average, four to six applications, when the image is to be seen by reflection, and twelve to fifteen for those which are to be seen by transparency. During this operation of reinforcement the images are washed three or four times in alternate baths containing iodo-cyanides and alkaline cyanides; then, immediately afterwards, in sulphate of protoxide of iron, pyrogallic acid, or any other reducers of the salts of silver. The consecutive employment of baths of iodo-cyanides, and of alkaline cyanides, has the effect of completely dissolving the non-adherent silver precipitated over the whole plate in each reinforcing bath, and this without destroying the original image, which alone is intensified. The washings in the reducing bath rendering neutral the metallic surface, increase powerfully the ulterior action of the reinforcing baths. 8. The photographic image being developed, fixed, and reinforced, is immersed for several hours, either in a bath of chloride or nitrate of platinum, or in alternate baths of chloride of gold and nitrate of platinum, or, again, in baths of chloride of gold. During the steeping, the silver of the image is either partly replaced by platinum, by a mixture of platinum and gold, or by gold alone. The purpose of the different substitutive baths is in order that the colour and nature of the layer of silver of the image may be changed after vitrification. In fact, if it is desired to obtain by the muffle, and by the reactions of silicic or boracic fluxes, images of a greenish black, they are previously immersed in a bath of chloride or nitrate of platinum; if, on the contrary, a black colour be required, they are steeped successively in baths of chloride of gold and nitrate of platinum. When, lastly, gilt images are to be produced, they are plunged into baths containing exclusively salts of gold. 9. The image, on coming from the platinum or gold baths, is washed in a solution of alkaline cyanide or concentrated solution of ammonia; it is then covered with a thick varnish of caoutchouc, or with gutta-percha, and submitted to the action of fire, in a muffle, when the organic matters are consumed and the metal left. 10. Lastly, the image, thus freed from the collodion and other organic matters, is covered with a silicic or boracic glaze, and submitted to an orange-red heat, which vitrefies it. This method is calculated to effect the perfect preservation of photographic images.

Group V.—Class 44: *Chemical and Pharmaceutical Products.*

The glass case of Messrs. John Casthelaz & Co., of Paris, contains a very rich collection of chemical products obtained by newly-improved processes, which reflect great credit on the firm. We shall enumerate them rapidly. They decompose daily two tons of nitrate of soda by sulphuric acid to obtain either nitric acid, monohydrated nitric acid of 48° to 50°, or pentahydrated from 36° to 40°. Nearly all these acids are employed on the very spot where they are produced. The monohydrated acid serves to produce the nitrated products of benzol and toluol; the acid at 35° is used to transform arsenious into arsenic acid, phenic acid into trinitro-phenic or picric acid, the bichloride of naphthaline into phthalic acid, &c. They transform daily a ton of benzol into nitrobenzol and aniline, and fabricate, on a very large scale, picric acid, crystallised and fused. The weight of some of the specimens attains one or even two kilogrammes. They have invented also, for purchasers, an apparatus termed *picrometer*, which permits them to verify, without trouble, the purity of the acid delivered. Starting with the fact, noticed by MM. Paris and Ernest Depouilly, that the basic phthalate of sulphate of lime at 300° is changed into benzoate of lime, they make naphthaline serve for the production of benzoic acid. Phthalic acid results from the decomposition of the naphthalic bichloride. Phthalate of ammonia distilled gives phthalimide of lucuine; distilled with powdered quicklime, the phthalimide produces benzonitrile, and benzonitrile distilled with caustic soda gives benzoate of soda, from which chlorhydric acid precipitates benzoic acid. Attacked by nitric acid, the bichloride of naphthaline leads to an oil, and forms binitrated chloride or the binitro-chloroform of M. Berthelot, of which the odour is so penetrating, and the action on the eyes and respiratory organs so terribly deleterious. The small vial of this oil which figures in the above-named glass case contains enough to burn the eyes of thousands of visitors. Near it we see the picrates of baryta, iron, lead, and mercury; chloroxynaphthalates of baryta, iron, zinc, nickel, and copper; with the bichromate of potash aniline violets, the soluble garnet colour, isopurpicrate of potash, a fulminating substance which must be kept wetted with water, the product of the reaction of cyanide of potassium on picric acid, which dyes wool in the richest colours with a saving of 25 per cent.

The pure and crystallised products from the laboratory of Messrs. Coblentz Brothers—phenotoluol, azobenzol, nitranilines, binitrobenzol, binitrotoluol, toluyldiamine, and paraniline—do them the highest honour. They are eminently skilful in transforming into colouring matters the direct products of coal tar. They exhibit an enormous block of nitrotoluol admirably well crystallised, of a pale yellow colour, and nearly free from nitrobenzol. They have discovered a very cheap process for transforming nitrobenzol into aniline, and nitrotoluol into toluidine. They take cast-iron turnings, roughly ground to powder, cover them with a layer of metallic copper, by plunging them in a solution of sulphate of copper. These galvanised turnings are then placed along with nearly an equal quantity of non-galvanised turnings, and surrounded by a sufficient quantity of water. Nitrobenzol or nitrotoluol is then added, and a galvanic action takes place in the liquid. The water is decomposed, and the hydrogen makes the nitrate body pass into the state of aniline or toluidine, which is then rectified and rendered pure. By treating the residues with sulphuric acid, the copper is dissolved, and can serve for another operation.

A magnificent and curious experiment will be made in a few days in the middle of the Exhibition, in the portion allotted to M. Flaud, one of the constructors admitted to furnish motive power for the gallery of machines. The experiment is imagined and organized by M. Henry Giffard, the well-known inventor of the injector; but it is to be produced under the name of Mr. Young, formerly the companion of M. Giffard in his steam essay of aërial navigation. It will consist of an anchored balloon, which will rise with twenty or twenty-five persons to a height of about a hundred metres. It will remain some time in the air, and then descend, to ascend again with a fresh party, and so on all day long. The problem of captive aërostation is, it is well known, one of the most difficult of physical mechanics. Arago said it was almost impossible. M. Giffard solves the question on the most rational side, and he will succeed. His balloon is a perfect sphere 21 metres in diameter, formed of two very fine and close tissues stuck together with several coats of black india-rubber American varnish, coated also with linseed drying oil to prevent all osmose or diffusion. This cloth is sufficiently impermeable to hydrogen to keep it in for a time sufficient for prolonged experiments, even for a whole day. The dimensions of the balloon are calculated so as to assure an ascensional power in such a manner that the horizontal component of the wind will only produce a slight deviation in the vertical direction of the cable holding the balloon. Upon this depends all the successful solution of M. Giffard, and it is certain that the angle of deviation will never exceed 40°. The cable unrolls and rolls up on a drum-wheel very solidly fixed. The hydrogen for the balloon will be temporarily procured by the ordinary process—iron and sulphuric acid; but in a few weeks it will be obtained by the decomposition of water by red-hot charcoal, at a price less than 15 c. the cubic metre. Oxygen of M. Tessié de Mothay at 50 c., and Giffard's hydrogen at 15 c. the cubic metre! What a fortunate combination this will make for the use of many industries!

We must not forget to mention, in a few words, the celebrated proprietor and director of the Pont-Labbé works, a real model establishment, M. L. Paisant. Founded in 1840, for the manufacture of starches and their conversion into alcohol, syrup, and dextrine, it was very soon affected by the potato disease. The establishment is not now confined to its original manufactures; it produces all sorts of chemical substances from the seaweed so abounding on the Brittany coast. It consumes at present 1800 tons of raw material, and delivers to commerce in places far inland 160,000 litres of kelp or lixiviating ash produced from seaweed. It is extensively used as an excellent manure over a great portion of Finisterre.

M. Paisant is a great manufacturer, much esteemed by all the inhabitants, and the jury should take him into consideration. He has developed his establishment on a large scale; he has paid great attention to the welfare of the population among which he dwells, and has ameliorated the condition of the working classes physically and morally, increasing their wages, constructing their dwellings, which leave nothing to be desired as to salubrity, and has founded a mutual helping savings bank, in case of the stopping of work or sickness, and for the relief of women and children.

In the first rank of the manufacturers of chemical products we must place M. Deiss, of Paris, Marseilles, and Lyons, the originator of the fabrication of sulphuret of carbon, and its use in the extraction of all fatty matters. In 1847, sulphuret of carbon, produced in a laboratory, cost 60 francs the kilogramme. In 1867, M. Deiss sells it at the rate of 35 centimes (3½d.) a kilogramme. In 1848 the treatment of caoutchouc by sulphuret of carbon was hardly known. Sulphuret of carbon now takes up, from the residues of many industries, several millions of killogrammes of fatty matters hitherto thrown away; and this application is one of the most brilliant discoveries of modern times. No matter how powerful the presses, a considerable quantity of oil is left in the cakes of oleaginous seeds. The sulphuret of carbon supplies, wonderfully, a remedy for this imperfection, by taking out all the remaining oil. Paris, Brussels, Lyons, and Marseilles possess large establishments for the extraction of the hitherto lost fatty matters. Since 1862, these industrial works have been well appreciated by the juries. Dr. Hofmann placed them in the first rank. Since a few years back, they have attained an enormous size. At the Carthusian Friary of Marseilles, Boulevard Achard, a gigantic extractor treats, in 36 hours, 43 cubic metres of pulp or lees of olive, using 45 tons of sulphuret of carbon, which penetrates into the whole mass, takes up the oil, and deposits it in the distilling apparatus. The sulphuret of carbon is then passed through a worm, regenerated, and condensed, without any sensible loss, ready to take up another quantity of oil. Thirty to thirty-five tons of oily substances are thus extracted at each operation.

At Lyons they used to throw into the Rhone, annually, the oil that might have been used for making 5000 tons of soap. Now, on the contrary, the application is complete: oil in its neutral state is entirely utilised, and the process of M. Deiss is welcomed in the industrial arts.

M. Collas, our esteemed friend and neighbour, No. 8, Rue Dauphine, was the first to introduce in France, about 1840, the manufacture, mechanically, of medical lozenges. They are stamped out as in the Mint, like coins of different shapes, and bear inscriptions indicative of quality and the method of using them. He discovered, in 1848, benzine in coal oil, and at once introduced it into commerce for cleansing stuffs; also nitro-benzine, which is a cheap substitute for the essence of bitter almonds. The creation of this substance really led to the beautiful aniline colours. The Society of Mulhouse said of him, in their meeting of March 22—"M. Collas has introduced into commerce benzine and nitro-benzine; the first seems for taking out stains from stuffs, the second is used in perfumery; . . . . he has not found out any colouring matter, but we are now in possession of a product hitherto impossible to be procured. Dr. Hofmann repeated the experiments of M. Runge on kyanol (aniline). . . . . Perkin reproduced a reaction first indicated by Berzelius, and a great industry has been created. . . . ." Thus the Mulhouse Society give all the credit to M. Collas for the means of making aniline colours.

Phosphates of lime, considered in the light of physiology and pharmacy, have been one of the favourite studies of M. Collas. He discovered and demonstrated by experiment that gelatinous phosphate of lime possessed the singular property of facilitating the putrefaction of animal matters. It acts under these circumstances not as forming, but as aiding powerfully, the development of those infusoria which determine the decomposition of animal matters. Thus it is a powerful digestive agent, and as experiments prove that diabetes and glucolucie depend upon the nature of the blood, and that the excellent preparations of phosphate of soda of M. Collas, his phosphoric lemonade, and milk of hydrated phosphate of lime are most successful.

During these last years, stimulated by the experiments of M. Lucie, M. Collas prepares iron reduced by electricity, quite pure, by aid of one Bunsen pile acting on chloride of iron in solution. The iron is deposited as a coating, while the several impurities fall to the bottom, leaving the iron quite pure. Obtained thus in grains or in very friable plates, it is easily reduced to an impalpable powder, like the copper of M. Oudry. It is, however, very oxidisable, and is obliged to be enclosed, for medical use, in gelatine capsules. Each capsule full of iron weighs 10 grammes and 50 centigrammes (or about 162 grains); the maximum dose per diem is five capsules, and observations continually prove the striking efficacy of the administration of metallic iron.

We recollect having seen in the glass case of M. Rousseau, another first-class maker of chemical products, a great phial of iron reduced by electricity, which was very astonishing to behold. It was not black like that of M. Collas, but it had the grey metallic colour of iron. He founded in 1843 an establishment for the fabrication and sale of chemical products and apparatus necessary for physical manipulation and the instruction of students. For twenty years he resided in the Rue de l'Ecole de Médecine, and three years ago he removed to the Rue des Ecoles. His customers have increased daily under our very eyes, and this augmentation proves that he has well fulfilled his engagement towards the public. In class 44, M. Rousseau shows what he ordinarily manufactures and delivers for sale:—1. Specimens or samples of products and reagents. 2. A series of oxides and salts for colouring silicates, the cost of which he has lowered without diminishing the quality, so as to compete favourably with foreign markets. 3. Masses of sodium that he was the first to manufacture commercially and cheaply, so as to render aluminium available at a moderate cost, and on which account M. Sainte-Claire Deville made him one of his partners. 4. Magnesium also prepared for sale commercially, along with other metals recently discovered—such as cæsium, rubidium, thallium, &c. 5. Pyrogallic acid for photographic purposes, of which he sells 1500 to 1800 kilogrammes per annum. 6. Benzoic acid employed in the preparation of aniline colours; of this he undoubtedly extracts several thousands of tons every year from the urine of cows, carefully collected from the numerous dairies about Paris. Before he began his work all the benzoic acid consumed in France came from Germany. The great aim of M. Rousseau is to give to the commercial world, at a reasonable price, materials which were unattainable with profit by the manufacturing world. He exhibits in Class 51 a stove, which advantageously replaces that of Gay-Lussac, and which only costs 25 fr. instead of 45 fr.; a new densimeter easily employed; plates and cylinders of artificial carbon for the cheap use of Bunsen's batteries. He also shows in Class 90, marked at the price of 200 fr. (8*l.*), a collection of products for the elementary instruction of chemical students, with an explanatory volume. We mention other innovations made in France by the same distinguished hand. In 1839 he patented the first process for obtaining sulphuric acid from pyrites; there was at that time a great establishment at Javel, but sulphur, then at a high price, suddenly fell in the market, and pyrites could no longer compete with it. To M. Rousseau is due, also, the first idea of the agglomerated coal, or "Charbons de Paris," extensively used in France for culinary purposes. M. Popelin-du-Cazze, who bought the patent, has been very successful on the large scale. In 1849 he organised the mode of extraction of sugar by the double action of lime and carbonic acid, which has now been followed for the last twenty-four years under the name of Rousseau's process by all Europe. He also discovered a decolorising charcoal black at a cheap price—6 fr. the 100 kilogs. (220·5 lbs.) for refining, in place of the cumbersome and dirty substances formerly used.

M. Huillard, the elder, of Paris, exhibits as the special objects manufactured by him orseille, orcine, orceine, eriphthine, eryphic acid, &c. The other mineral substances, the protoxide and sesquioxide of cobalt, and five carbonates, the arseniate, phosphate, silicate, borate, sulphate, nitrate, and chloride of cobalt; and the carbonate, nitrate, and chloride of cadmium are admirably crystallised. These are very creditable, and reflect much honour upon M. Jourdin, the young and energetic superintendent of the works, who is actively engaged in solving the following problems:—1. The delivery to commerce of orseille, liquid orseille, orcelline, extract of orseille, or imperial red. 2. The production on a large scale of cobalt blues to rival those of Germany. M. Huillard has succeeded in rendering lower the price of cobalt blues for stuffs and wall-paper, while at the same time they are more durably fixed. The Bank of France has adopted them for the 100 fr. bank-notes, inimitable by any photographic process; also for the 20 centimes (blue twopenny) postage stamps, though they are of a greenish hue by candle-light, but readily distinguishable from the others.

M. Eusèbe, of Paris, exhibits some very fine aniline greens and reds obtained by carbò-humic acid. He has yielded the full right of manufacture to M. J. J. Müller, of Basle. He has two magnificent collections of samples which can rival with any of the other manufacturers in the Palace.

M. Jean Rod has already received our compliments for the splendid specimen of crystallised and almost white rosaniline. He challenges the first markets of Paris or London, and the greatest houses to produce better. He produces daily 175 kilos. of muriate of rosaniline, aniline blues, violet, and greens. He also produces, with the same substances, and delivers to the commercial world—hydrochlorate of aniline, a red dye; hydrate of monophenylic rosaniline, giving a reddish-violet tint; hydrochlorate of diphenylic rosaniline, giving a blue violet; hydrochlorate of triphenylic rosaniline, giving a blue dye.

In another collection of violets exhibited by him under the name of Parma or Alexandria violet, in the preparation of which ethyl replaces phenyl—Hofmann's process—exhibited also by M. Menier, M. Rod exhibits a cup of 500 grammes (1⅛ lb. avoirdupois) of cyanide or quinoline blue. To enumerate the splendid display of M. Rod would be too much for our space; suffice it to say that we warmly recommend him to the attention of the jury.

London University.—Professor Williamson, Ph.D., F.R.S., and H. Debus, Esq., Ph.D., F.R.S., have been re-elected Examiners in Chemistry for the University of London. The salary of each office is 175*l.* per annum.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, April 18.

Dr. J. H. Gladstone, *F.R.S., Vice-President, in the Chair.*

In continuation of our report of last week, we now give an account of the papers read by Mr. Chapman, and of the short communication from Dr. F. C. Calvert.

The first, entitled "*Oxidation of the Acids of the Lactic Series*," by Messrs. E. T. Chapman and Miles H. Smith, asserts that the acids of this series may be divided into two classes, according to the nature of the products of oxidation which they respectively furnish; the first containing hydrogen and an organic radical, giving rise to the formation of aldehydes, whilst the secondary acids, containing two organic radicals, produced ketones. Dimethoxalic acid yielded, on oxidation, acetone and carbonic acid, and ethomethoxalic acid (prepared from the corresponding ether of Frankland and Duppa) gave carbonic acid and methylated acetone, boiling at 82–83° C., and having a fragrant odour, very similar to propione. Of this compound an analysis was made, which furnished results in close accordance with the numbers demanded by theory. Like common acetone, it combines with alkaline bisulphites, but with more energy, evolving a considerable amount of heat, and forming a compound which is very soluble in water. On further oxidation of this substance nothing but acetic acid was produced. Similar results were obtained in the oxidation of diethoxalic acid. The authors recommend a resort to this method for the easy preparation of the ketones, and, finally, propose by this means to investigate problems of isomerism occurring amongst the fatty acids, illustrations of which are sketched in the paper.

The Chairman insisted upon the value of an extended optical method of research carried out in conjunction with the principles indicated by the authors in this communication.

A preliminary note "*On Limited Oxidation with Alkaline Permanganate*," by the same authors, was then read. The authors point out the differences in the products of oxidation of common alcohol by the use of acid and alkaline solutions of permanganic acid; thus, whilst, in the presence of sulphuric or other mineral acid, a mixture of aldehyde and acetic acid is produced, on the other hand, in an alkaline solution nothing but oxalic acid is formed. Lactic acid under like circumstances gave similar results. So that much depends upon the maintenance of unalterable conditions during the progress of oxidation with permanganate of potash, and the authors submit that Truchot's and Berthelot's anomalous results obtained in the examination of amylene are attributable to a want of appreciation on their part of this fact. The authors described a method of distinguishing between tartaric and citric acids, founded upon the circumstance that the latter acid does not carry the reduction further than the green manganate in a strongly alkaline solution, whilst tartaric acid furnishes the brown hydrated binoxide.

The Secretary then read a paper by Dr. F. Crace Calvert, "*On the Presence of Soluble Phosphates in Cotton Fibre, Seeds, &c.*" The author points out the fact that seeds contain relatively more mineral phosphates than other parts of the plants upon which they are borne, and alludes to the common practice of burning off the organic matters before proceeding to search for the phosphates therein contained. From his experiments Dr. Calvert has, however, been led to conclude that the whole of the phosphoric acid or phosphates is merely held mechanically distributed throughout the organic tissue, and in such a condition that they may be wholly extracted by the action of water. Cotton yarn steeped for several hours in distilled water furnished a solution containing appreciable quantities of phosphoric acid, lime, and magnesia, and quantitative experiments were made upon seven characteristic varieties of cotton, which had been carefully prepared and carded in Manchester, for the purpose of determining the extent to which the phosphates could be removed by washing. The results showed by the uranium process amounts varying between ·035 and ·055 per cent. of phosphoric acid thus dissolved, whilst traces only of this constituent could be detected in the ash left upon burning the washed and dried cotton. Similar experiments made upon wheat, French beans and walnuts gave like results, much phosphoric acid and magnesia being discovered in the aqueous solution. The author promises to continue these researches and communicate the results.

The Chairman moved a vote of thanks in favour of the authors, and adjourned the meeting as already reported.

Thursday, May 2.

Professor W. A. Miller, *M.D., Trea. R.S., Vice-President, in the Chair.*

On the minutes of the previous meeting being read, the Chairman stated that the election announced to have taken place on the last occasion must be declared null and void, by reason of an insufficient number of voters taking part in the ballot. The name of another candidate who was then returned non-elected would also be again suspended, since the ballot in both instances was informal. The minutes were then confirmed. The following gentlemen then signed the statute book, and were admitted Fellows of the Society, viz., Messrs. Henry Weston Eve, C. R. A. Wright, William K. Waite, and J. W. Hudson, LL.D.

The candidates now proposed for election were Augustus Alfred Wood, 74, Cheapside; William Phipson Beale, barrister-at law, Stone Buildings; and Alfred Coleman, Plough Court, Lombard Street. For the second time were read the names of Robert R. Tatlock, Millhouse, Kyles of Bute, and Walter William Fiddes, gas engineer, Sothernhaye, Clifton. For the third time were read the names of John Cargill Brough, 4, Norman Terrace, Stockwell; F. W. Peterson, of her Majesty's Mint, Calcutta, 51, Myddelton Square, London; and three other candidates. Before proceeding to the ballot, the Chairman said that the measure which had been under the consideration of the Council, and which was intended to raise the standard of qualification required for a member's admission into the Society, was not to be construed as being retrospective in its operation, and it would be manifestly inconvenient if the regulations were made more stringent in the case of the candidates proposed for election on this occasion. Upon the ballot being opened, the Fellows to the unusually large number of thirty-two recorded their votes, and the balls in certain instances had to be very carefully counted. The result was the return of Mr. Brough and Mr. Peterson as Fellows of the Society, but the other three candidates were declared non-elected.

The Chairman referred to the circumstance of so many of the leading members being in attendance at the Paris Exhibition and elsewhere, and said that a difficulty had been encountered in the attempt to provide formal matter in the shape of papers to be read; he would, therefore, invite communications from any Fellow or visitor in the room, who chanced to have any subject of interest in a sufficiently forward state to bring before the notice of the meeting.

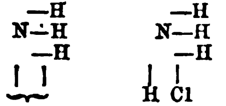
Dr. Odling claimed the indulgence of the meeting in regard to the remarks he was about to offer, with a view of starting a subject for discussion. In the first place, he would mention, for the information of the manufacturing chemists, that the French had apparently succeeded in working out a great commercial problem with respect to the recovery of sulphur from the waste residues of the alkali manufacture. Great blocks of sulphur were shown in the Paris Exhibition, which were said to have been prepared from this source, and it was proposed to employ it in making gunpowder and other sulphur products. So far as the speaker was aware, no published statement of the *modus operandi* had appeared, but it was generally believed that manganese in some form, and possibly the refuse of the chlorine retorts, was made available.[*] In the event of these antici-

---

[*] It has been suggested that the sulphur may possibly have been extracted by the method of M. Emile Kopp, described last year in the *Moniteur Scientifique*.—Ed. C. N.

pations being realized, there were vast accumulations of waste material in the north of England which could thus be economised. Turning to another topic of more abstract scientific interest, Dr. Odling observed that he found a difficulty in recognising the law of combination by saturation capacities, in what had been termed the "atomicity" of nitrogen. For instance, this element was found at one time entering into combination with *three* atoms of hydrogen, and thereby forming ammonia, whilst at other times, as in sal ammoniac, the nitrogen was united with *five* associated atoms. The constitution of these bodies might be thus represented:

I.—Ammonia. II.—Sal Ammonia.



According to this view, nitrogen had always five bonds, two of which, in the first example, controlled one another's activity, and all five were brought into play and united either with hydrogen or chlorine in the ammonia salt. In the union of chlorine and nitrogen, there must be an abstraction of heat, since the decomposition of the chloride of nitrogen was attended with the disengagement of a considerable amount of heat, yet, if chlorine be passed into ammonia, there was still a development of heat, and, nevertheless, the chlorine we are told, leaves the hydrogen in order that it may unite with nitrogen, an element for which it has a very slight affinity. It might then, from this reaction, be doubted whether nitrogen was really pentatomic. Again, sodium exposed to air produces Na_2O. and this dissolved in water (with disengagement of heat) produced a hydrate, from which the water could not again be driven off by heat. But inasmuch as sodium gives out more heat than hydrogen by its union with oxygen, the conversion of the molecule of sodic oxide into hydrate would produce exactly as much cold as the conversion of the molecule of water into hydrate would produce heat. Thallium differed from sodium in these respects, and its hydrate lost water by the action of heat. These facts prove that sodium exerts upon the hydrogen an action which thallium does not. Other illustrations were quoted: thus in the slaking of lime there was great heat evolved, whereas the contrary result might have been expected, since there was, so to speak, "an unburning of the calcium." In the instances of barium and magnesium there seemed also something requiring explanation. The speaker concluded by offering an apology for having brought forward these considerations in an incomplete form, but he trusted that the attendant circumstances would justify his having taken such a step.

Professor Williamson remarked that chemists were very much in the habit of losing sight of one most important fact —viz., the changes of properties which elements undergo in combination. When they found that one element had got certain combining forces, they were apt to suppose that it must retain them when partially saturated by some other element. Thus, admitting that in potassic hydrate an atom of oxygen was combined, on the one hand, with an atom of potassium, on the other with an atom of hydrogen, it was not correct to assume that the force which bound it to the hydrogen was the same as that which bound it to each of the two atoms of hydrogen in water. The atom of oxygen in potassic hydrate was altered by its combination with potassium in such a way that it combined more powerfully with hydrogen than in water. So also in sal ammoniac, an atom of nitrogen was united with five atoms, four of hydrogen and one of chlorine. By uniting with hydrogen it had become more basylous, and could hold chlorine more firmly than it could do when united only with chlorine. Professor Williamson added a few remarks on the subject of the word "atomicity." He was of opinion that all we know on the subject was represented by the word equivalence, and he recommended the retention of the word equivalence. "Atomicity" was used by some persons to denote an immutable equivalence, and in such sense was untrue and mischievous.

The Chairman entertained an objection to the use of the word "atomicity," since it implied a theory, whilst the term "equivalence" was merely a statement of the facts.

Dr. Thudichum said that in taking note of the fact that three successive speakers had expressed their dissatisfaction with the term "atomicity," he begged to state that he had never used it, but had from the beginning of his teaching described the property of atoms which it was intended thereby to signalise as "dynamicity." He recognised a priority of publication of the conception of the necessity for this change on the part M. Würtz,* although this chemist had not made the change nor abandoned the questionable word. No one who valued logic could use expressions which signified the "indivisibleness of the indivisible," or the "undividness of the undivided," with the effect of thereby defining anything; but the expression would appear still more illogical when it was considered that it was used to define a power the very essence of which, as it appeared from one point of view, was divisibility. Indeed, the expression "tomicity," if properly understood to refer to the power, and not to the matter or body of the atom, would be correct for a far greater number of cases than the same word with the privative "a" prefixed could ever reach. Those who had hitherto been most active in developing the theory of "atomicity" had implied that it was a power possessed by the atom absolutely, and that in cases where apparently only a portion of the maximum power which an atom could exercise was employed, the rest of its power was free, and open to engage itself. Late developments of science had, however, made it very doubtful whether this was a correct appreciation of the facts observed, and whether the changes in the amount of power exhibited by atoms were not actual changes of the amount of power possessed by them in concrete cases. Indeed, if he had rightly understood some theoretical considerations of Kolbe and of Würtz, these chemists seemed to admit that what they called "atomicity" was a changeable power of atoms, and that was the conclusion towards which his own studies and reflections had been driving him (Dr. Thudichum) for some time. The positive part of his opinion would appear from a few definitions which he begged leave to lay before the meeting. The idea of atom included, of course, that of element, in the chemical sense; and most chemists defined atom as the smallest quantity of an element that could exist in any chemical compound. All atoms manifested various qualities of power, and of some qualities of power many atoms manifested varying quantities. The first obvious power of atoms was that of polarity, the differentiation of which, in two opposite qualities (conveniently termed positive and negative, or + and −), explained the formation of the elementary molecule, or molecule consisting of two atoms homogeneous in every respect except that of polarity. Atoms further manifested chemism, or power to effect interchange of place, or substitution, or combination with heterogeneous atoms, polarity determining the place which each atom should take with reference to any other. Chemism is a stronger power than more polarity; it separates the homogeneous molecule; but, in forming a new and heterogeneous molecule, it adds the entire amount of the polarity of the atoms employed to its own effective power. Thus, out of the combination of a molecule of hydrogen $(\overset{+\,-}{HH})$ and a molecule of chlorine $(\overset{+\,-}{ClCl})$, there result by the action of chemism two molecules of hydrochloric acid, equal in all respects except the polarity of their constituent atoms. The next quality which atoms manifested was dynamicity, which might be defined as the faculty to vary—that is, to decrease and increase—the amount of power of combination with other atoms. This power might be exercisable in multiple directions at the same time, but was not separable as to seat. For the intensity with which an atom was held, or exercised

---

* The reader is referred to the footnotes, p. 184 of Würtz's "Philos. Chimique." Paris. 1864.

itself, in combination, dynamicity afforded as yet no measure. That intensity was no doubt the result of polarity, chemism, and dynamicity, and probably other influences, combined. But for the numeral quantity of power or the number of units of power of combination as measured by certain assumed standards, dynamicity afforded a correct expression. The unit or minimum of dynamis manifested by an atom, he termed monad; the greatest number of units constituted its monado-atomic equivalent, or full dynamis. The assumed standard of unit of dynamis hitherto accepted had been hydrogen, and the maximum number of units of power, or monads, hitherto attributed to any atom had been six, or once, in the case of iodine, seven. Now, the great error of the atomicity doctrine, most useful as it had been in evolving new facts and ideas, was this, that it assumed the number of monads of the atoms of each element to be invariable. The application of the doctrine of dynamicity to a broad field of chemical facts would, however, soon show that the dynamicity of atoms was variable, called forth or imparted by influences external to the atom, and similarly withdrawn. Heat, light, electricity, vital power, and pathogenetic power were such influences, governing not only the polarity and chemism, but also the dynamicity of atoms. Hydrogen manifested itself most commonly as monodynamic; it could be substituted by iodine and nitrogen. Now, iodine might be tridynamic, as in ICl_3; nitrogen might be tridynamic, as in ammonia. In the latter case the defenders of the invariable pentadynamicity of nitrogen would say that it was only active with three monads, and that two were free. In the case of iodine, however, when it substitutes hydrogen, the assumption that it only functioned with one monad out of its three was inconvenient, as it opened the door to the admission of the same variability on the part of hydrogen, and therefore iodine was here commonly admitted to be monodynamic. When nitrogen was made to substitute hydrogen, it lost apparently all dynamicity, though exercising only one, according to the assumption of the invariable monodynamic character of hydrogen. Out of such difficulties there were, no doubt, ingenious modes of extrication, such as the assumption of molecular powers on the part of combined groups of atoms not having the character of radicals. But the simplest cases were most simply explained by the hypothesis that the dynamicity of an atom was variable and dependent upon external influences calling forth its manifestation. Iodine had already been shown to be monodynamic and tridynamic; in imide, nitrogen was as monodynamic as when it substituted hydrogen in azobenzoic acid; in amide, nitrogen was didynamic; in ammonia the atom of nitrogen exhibited tridynamic combining powers; in some of the compounds lately discovered by Griess it showed tridynamic substitution power, replacing three atoms of hydrogen. The generalisation of this conception would no doubt destroy the simplicity of the present doctrines, but lead to a better appreciation of all the powers and influences determining combination or separation. In conclusion, the speaker apologised to the Society for the imperfection of his remarks. They had been quite *impromptu*, and dealt with a great and difficult subject, which in many respects required consequential development. But he recommended his terminology[*] to the attention of the members, feeling sure that a slight familiarity with it would prove its great convenience.

Professor **Foster** agreed with Dr. Odling that, when the two molecules Na_2O and H_2O were converted into $2NaHO$, the change undergone by one molecule was the converse of that undergone by the other, and, therefore, that it was difficult to understand that the quantity of heat developed in the one case should differ from that absorbed in the other; but he observed that there was no direct proof that the reaction in question was attended with any evolution of heat: when water acted on oxide of sodium, a great part of the observed evolution of heat was certainly due to the combination of NaHO with excess of water, and it remained to be proved that this action was not the source of the whole. The conversion of BaO and H_2O into BaH_2O_2 he regarded as a reaction not perfectly comparable with the above, since, in this case, the two molecules BaO and H_2O coalesced into the single molecule BaH_2O_2. With regard to the different behaviour of what appeared to be similarly constituted molecules when subjected to the same treatment, as, for example, that of sodic and thallic hydrates at high temperatures—an instance to which Dr. Odling had referred—he considered that the explanation of them was to be sought in the influence exerted by each atom in a complex molecule upon the properties of all the rest. To help in forming a definite conception of the way in which such an influence might be exerted, he suggested that a diatomic atom (such as O) might be compared with a magnet with its two poles, while monatomic atoms (such as Na and H) might be compared with a single isolated magnetic pole, if such a thing were capable of existing. Then just as the south pole of a magnet would be strengthened by induction on bringing another south pole into contact with its north pole, so by bringing an atom of sodium into contact with one pole of an atom of oxygen, the attraction of the other pole for atoms of a certain kind might be increased, although its attraction for sodium might be lessened. If this comparison of a diatomic atom with a magnet was admitted, he pointed out that, in all cases, if an atom of a given kind applied to one pole of a diatomic atom tended to strengthen the polarity of the latter, an atom of the same kind applied to the other pole would tend to weaken it in an equal degree; and hence that, as a general rule, if two symmetrical molecules, such as NaONa and HOH, came together, the forces with which the atoms were held together would be, on the whole, increased by an interchange of atoms such as would convert the above molecules into NaOH and NaOH. Professor Foster added that he did not offer these remarks as affording a solution of the difficulties pointed out by Dr. Odling, but simply as indicating a direction in which he thought such a solution might reasonably be sought for.

Mr. **Chapman**, in allusion to an illustration made use of by the last speaker, said that if two bar magnets were placed end to end, the north pole of one being adjacent to the south pole of the other, the sustaining power of the free end of the lower magnet was *not* augmented; but that if they were laid parallel and alongside, with similar poles adjacent, the magnetic energy of each magnet would be greatly increased. (This statement was received with manifest indications of dissent.)

Professor **Wanklyn** had likewise a great objection to the continued use of the word "atomicity." Ammonia and salammoniac presented differences in constitution which were not easily explained, but it might happen that the *hydrogen* in these compounds had different values.

The meeting was then adjourned until Thursday, the 16th instant.

Thursday, May 16.

F. A. **Abel**, Esq., F.R.S., *Vice-President, in the Chair.*

The minutes of the previous meeting were read and confirmed; Mr. F. W. Peterson was formally admitted a Fellow of the Society; and the names of William Phipson Beale, barrister-at-law, Stone Buildings; Alfred Coleman, Plough Court, Lombard street; and Augustus Alfred Wood, 74, Cheapside, were read for the second time.

Mr. **Perkin**, F.R.S., said he had a few observations to make upon some experiments with which he had been lately engaged. Coumarine, it is well known, is the crystalline principle of the Tonka bean, and was first analysed by Delalande and afterwards by Bleibtren. The formula of this substance is $C_9H_6O_2$. When heated with potash, it assimilates an equivalent of water, and becomes converted into coumaric acid $C_9H_8O_3$. This, again, if fused with potash, yields salicylic and acetic acids, with evolution of hydrogen. On account of this latter transforma-

---

[*] In Dr. Thudichum's Tables of New Atomic Weights, Molecular Weights, and Functional Types for the Lecture-room and the Study, published by Hardwicke, Piccadilly, this terminology is adopted, and the theory of the variable dynamicity of atoms indicated on the basis of some of the best-established facts.

tion, coumarine is viewed as a derivative of salicyle. Having been lately a good deal engaged with the study of salicyle derivatives, he had often endeavoured to obtain some clue to the constitution of coumarine, hoping that he might eventually be able to build it up from some salicyle compound. About ten days or a fortnight ago he obtained a beautiful crystalline product, possessing both the odour and composition of coumarine. When heated with potash, it yielded an acid, apparently identical with coumaric acid, and on fusing it with potash it was converted into salicylic acid—it was, in fact, artificial coumarine. He had not compared it side by side with the natural product, but expected to do so in the course of a few days. As he hoped shortly to bring an account of his results before the Society, he would refrain from entering into further details, except to state that he obtained his product from the sodium derivative of salicyle by means of acetic anhydride. Knowing the interest that chemists generally take in the artificial formation of natural products, he thought these remarks would not be unacceptable.

An elaborate paper "*On the Constitution of the Phosphites*," by Professor C. **Rammelsberg**, was read by the Secretary. The author commences with an historical notice of previous researches, which appear to have left unsolved the amount of water, or rather the condition of the hydrogen, contained in the salts of phosphorous acid, so that the constitution of these bodies might be represented by one or other of the following formulæ:—

$$H_2R''_2P_2O_6 \text{ and } H_4R''_2P_2O_7.$$

To elucidate this question, the author prepared and analysed a great many different phosphites, and the results in the case of the dyadic metals warrant the adoption of the second formula. Thus the barium aud nickel salts have precisely the above composition, the strontium and calcium salts containing extra two atoms of water, and magnesium salts were prepared containing respectively five and twelve atoms of water of crystallisation. Zinc and magnesium appear, however, to give rise to the production of salts of two classes, whilst lead, copper, manganese, &c., always form compounds containing one atom of hydrogen which cannot be replaced by a metal.

Class A.	Class B.
HK_2PO_3	$H_4Ba_2P_2O_7$
$HMnPO_3$	$H_4Ca_2P_2O_7$
$HZnPO_3$	$H_4Mg_2P_2O_7$
$HPbPO_3$	$[H_4Zn_2P_2O_7]$
$[HMgPO_3]$	

Phosphorous acid seems to be incapable of forming acid salts. The crystallised acid itself contains one atom of water, and any attempt to expel the latter by the application of heat destroys the substance, with evolution of gaseous phosphide of hydrogen.*

After the **Chairman** had moved a vote of thanks to the author, and invited discussion upon the subject of the communication,

Dr. J. H. **Gladstone** said it was sometimes easy to build up a compound and speculate upon its constitution, if we knew already the nature of the body from which it was prepared. The starting-point in this case was the terchloride of phosphorus, which, undergoing decomposition by water, furnished the acid in question:—

$$PCl_3 + 3H_2O = 3HCl + H_3PO_3.$$

The acid itself was stated, by Prof. Rammelsberg, to have the following composition:—$H_4P_2O_5 + H_2O$. To obtain this result, there were two stages, the first or intermediate product being the oxychloride of phosphorus—

$$\text{I. } 2(PCl_3) + \left.\begin{matrix}H\\H\end{matrix}\right\} O = \left.\begin{matrix}PCl_2\\PCl_2\end{matrix}\right\} O + 2HCl.$$

$$\text{II. } \left.\begin{matrix}PCl_2\\PCl_2\end{matrix}\right\} O + 4H_2O = \left.\begin{matrix}P(HO)_2\\P(HO)_2\end{matrix}\right\} O + 4HCl.$$

The **Secretary** then read a paper by Dr. A. **Dupré** "*On the Changes in the Proportion of Acid and Sugar present in Grapes during the Process of Ripening.*" It has frequently been inferred that the tartaric and malic acids in grape-juice become transformed into sugar during the process of ripening; but the author's experiments tend to disprove this assertion. Dr. Dupré collected and experimented upon a hundred berries of Riesling grapes gathered at intervals of a month, commencing with September last, and the amounts of tartaric acid, free and combined, and also of sugar, were determined in the separated juices. The proportion of sugar increased in order of time from 2·98 to 12·10 and even to 16·2[illegible] per cent. in the juice of the perfectly ripe fruit; whilst the entire berries showed but a slight diminution or no appreciable change in the total amount of acid present. The saccharine matter could not, therefore, have been directly derived from the organic acid or its salts contained in the grape; but the author thinks it possible that the presence of such acid effects a change resulting in the production of sugar similar to that known to occur in the conversion of starch into sugar by the action of sulphuric and other acids. Further experiments, even more decisive in their character, were made upon Gutedel and Muscatel grapes, gathered at the same time and from the same vine, but in various stages of ripeness. In some of the unripe berries there was absolutely no sugar, whilst in others nearly ripe 8·87 per cent. of sugar was found; but the amount of free acid estimated in a hundred grapes was almost the same in three samples of Gutedel, and actually increased with the ripening of the Muscatel.

Another paper, by the same author, was then read. It is entitled, "*On some of the Effects produced by the Addition of Plaster of Paris to Must.*" It seems to be a common practice in the wine-growing countries to add the substance named in the heading to grape-juice either before or during the process of fermentation, the alleged object being to increase the richness of the must by the absorption of water. Although this action doubtless occurs, the author points out that the loss of material in the course of such treatment (by mechanical retention in the gypsum) never compensates for the augmentation of sugar in the remaining juice, and suggests that a partial evaporation should be resorted to, or some sugar added instead of the earthy sulphate. Numerical results are quoted in support of this assertion, and the chemical changes induced by the employment of the plaster are fully stated. Consisting, as it does, of sulphate with a little carbonate of lime, it not only decomposes the tartrates in the grape, with liberation of the purgative sulphate of potash, but also neutralises and removes some of the free tartaric acid—an essential constituent of wine—leaving the malic acid still soluble, thus deteriorating, says the author, the condition of the juice, and assimilating it to the quality of that obtained from unripe fruit. Wine made according to the above system will be characterized—1st, by a more or less complete absence of tartaric acid; 2nd, by containing sulphates in solution; and 3rd, by giving, on incineration of the residue, a larger proportion of ash and diminished amounts both of phosphate and carbonate.

Dr. **Odling**, in answer to Colonel **Yorke**, said that chloride of barium always indicated the presence of dissolved sulphates in sherry, but gave no precipitate in a true claret.

The **Secretary** then proceeded to describe "*An Adapter to be used in connexion with Sulphuretted Hydrogen Apparatus*," by the Rev. B. W. **Gibsone**, M.A., B.Sc. This arrangement consists of an ordinary glass funnel, the limb of which fits into a conical bung of vulcanised india-rubber, whilst the top is covered with a flat plate of the same material, perforated with three holes, through one of which a current of sulphuretted hydrogen is made to enter, another aperture serving as the exit pipe for the excess of gas, which it is proposed to absorb by passing through a succession of Woulff's bottles charged with ammonia. The third is a spare hole usually closed with a stopper. Within the funnel itself is a long glass

---

* An earlier statement respecting the phosphites, by the same author, appeared at page 241 of the present volume.—Ed. *C. N.*

tube, with a thistle-shaped expansion at top, into which is fitted a cork and short piece of tube for connexion with the central aperture above it, and this funnel tube has also within it a cane of glass rod of greater length than itself, with a bead placed inside the thistle as a means of lifting it from close contact with the apex of the larger funnel, which is kept moistened with water. When thus lifted a current of the gas makes its escape from the lower orifice of the funnel, and is made available by passing through any solution contained in the bottle to which the bung and adapter are fitted. When the action is completed the flow of gas is stopped simply by removing the vessel, when the weight of the glass rod causes the funnel tube to descend, and no more gas can pass. For a description of his sulphuretted hydrogen generator the author referred to a sketch of the apparatus which had already appeared in the Chemical News (*vide* p. 240 of present volume).

An elaborate paper "*On the Practical Loss of Soda in the Alkali Manufacture*," was then read by Mr. C. R. Wright, B. Sc. The author has had an opportunity of studying the minute details of Le Blanc's process as carried out in a large factory making upwards of 150 tons of alkali weekly, and the products were examined at every stage for the purpose of ascertaining the loss of soda during the process of conversion. A capital series of analyses are given, which show the average composition of salt cake, black ash, soda ash, refined ash, and the dried vat waste, which last seems to contain a notable quantity of alkali, both in the soluble and insoluble states. The total loss of sodium in the process of converting salt into refined soda ash is set down at 20·24 per cent., and consists of the following items:—

	Per cent.
Previous to Lixiviation.	
Sulphate of sodium left undecomposed	3·49
Insoluble sodic compounds formed	5·44
Volatilisation of sodic compounds	1·14
During and after Lixiviation.	
Soluble alkali left in vat waste	3·61
Oxidation of sulphide of sodium	—
Leakage and losses in white ash process	6 56
Total loss	20·24

The speaker made reference to the previous researches of Mr. Kynaston,[*] and also to those of Mr. James Hargreaves lately published in the Chemical News. The last-named gentleman affirms that one-seventh part of the chloride of sodium escapes conversion into sodic carbonate or is lost in the process of manufacture.

The Chairman moved a vote of thanks to the authors of the respective communications, and, at a late hour, adjourned the meeting until June 6, when Sir Benjamin Brodie will deliver a lecture "*On Ideal Chemistry.*"

ROYAL SOCIETY.

Thursday, May 2, 1867.

At the usual weekly meeting this evening the President read from the chair the names of the following fifteen candidates recommended by the Council for election. They will be balloted for on June 6:—William Baird, M.D.; W. Boyd Dawkins, Esq.; Baldwin Francis Duppa, Esq.; Albert C. L. G. Günther, M.D.; Julius Haast, Esq., Ph. D.; Captain Robert Wolseley Haig, R.A.; Daniel Hanbury, Esq.; John Whitaker Hulke, Esq.; Edward Hull, Esq.; Edward Joseph Lowe, Esq.; James Robert Napier, Esq.; Benjamin Ward Richardson, M.D.; J. S. Burdon Sanderson, M.D.; Henry T. Stainton, Esq.; Charles Tomlinson, Esq.

QUEKETT MICROSCOPICAL CLUB.

The usual monthly meeting was held at University College on the 26th instant, Mr. Ernest Hart, President, in the chair.

Dr. Halifax described his ingenious method of obtaining thin sections of insects, soft vegetable tissues, minute seeds, &c., by immersion in wax, and afterwards slicing them upon the ordinary section table.

Mr. Higgins gave a lengthened and interesting description of the "otolithes" or earbones of fishes, to the study of which he has devoted himself with remarkable industry for the last eighteen years. The result of many thousand examinations of fossil and recent fish has enabled him with positive accuracy to identify species, and in many instances genera. His remarks were illustrated by an extensive series of "otolithes," which were displayed in cases in the room, containing specimens obtained from the largest to the smallest fish, both freshwater and marine.

The meeting, which was attended by upwards of 130 members and their friends, terminated with a *conversazione.* Eight members were elected.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting. April 16, 1867.

Edward Schunck, *Ph.D., F.R.S., &c., President, in the Chair.*

Mr. Henry Charles Beasley was elected an ordinary member of the Society.

"*On a New Form of the Dynamic Method for Measuring the Magnetic Dip*," by Sir William Thomson, M.A., D.C.L., F.R.S., &c., Honorary Member of the Society.

Seven years ago an apparatus was constructed for the natural philosophy class of the University of Glasgow, for illustrating the induction of electric currents by the motion of a conductor across the lines of terrestrial magnetic force. This instrument consisted of a large circular coil of many turns of fine copper wire, made to rotate by wheel work about an axis, which can be set to positions inclined at all angles to the vertical. A fixed circle paralled to the plane containing these positions, measured the angles between them. The ends of the coil were connected with fixed electrodes, so adjusted as to reverse the connexions every time the plane of the coil passes through the position perpendicular to that plane. When in use, the instrument should be set as nearly as may be in the magnetic meridian. The fixed electrodes being joined to the two ends of a coil of a delicate galvanometer, a large deflection is observed when the axis of rotation forms any considerable angle with the line of magnetic dip. On first trying the instrument I perceived that its sensibility was such as to promise an extremely sensitive means for measuring the dip. Accordingly, soon after I had a small and more portable instrument constructed for this special purpose; but up to this time I had not given it any sufficient trial. On the occasion of a recent visit, Dr. Joule assisted at some experiments with this instrument. The results have convinced us both that it will be quite practicable to improve it so that it may serve for a determination of the dip within a minute of angle. I hope, accordingly, before long to be able to communicate some decisive results to the Society, and to describe a convenient instrument which may be practically useful for the observation of this element.

"*Observations on the Alteration of the Freezing Point in Thermometers*," by Dr. J. P. Joule, F.R.S., V.P.

Having had in my possession, and in frequent use, for nearly a quarter of a century, two thermometers, of which I have from time to time taken the freezing points, I think the results may offer some interest to the Society. Both thermometers are graduated on the stem, and are, I believe, the first in the country which were accurately calibrated. Thirteen divisions of one of them correspond to one degree Fahrenheit. It was made by Mr. Dancer, in the winter of 1843-44. My first observation of its freezing point was made April, 1844. Calling this zero, my successive observations have given

---

[*] *Journ. Chem. Soc.* xi. 135.

0	April, 1844.
5·5	February, 1846.
6·6	January, 1848.
6·9	April, 1848.
8·8	February, 1853
9·5	April, 1856.
11·1	December, 1860.
11·8	March, 1867.

The total rise has been, therefore, ·91 of a degree Fahrenheit. The other thermometer is not so sensitive, having less than four divisions to the degree. The total rise of its freezing point has been only ·6 of a degree; but this is probably owing to the time which elapsed between its construction and the first observation being rather greater than in the case of the other thermometer. The rise of the two thermometers has been almost identical during the last nineteen years.

"*On the Casting, Grinding, and Polishing of Specula for Reflecting Telescopes, Part IV.*," by James Nasmyth, Esq., C.E., Corresponding Member of the Society.

In this part of his paper the author gives detailed descriptions, illustrated by diagrams, of his methods of mounting the specula of reflecting telescopes, and of testing the figure of the great speculum; he also offers some very useful remarks on the general management of Newtonian reflecting telescopes, and on the atmospherical circumstances which affect their performance.

PHOTOGRAPHICAL SECTION.

April 9, 1867.

J. Baxendell, *F.R.A.S., Vice-President of the Section, in the Chair.*

Mr. Brothers read the following "*Note on Photography in 1787.*"

It is generally supposed that the earlier attempts to use nitrate of silver for producing pictures of lace, leaves, and other objects on white leather or paper were made by Wedgewood and Davy about the year 1802; but it will appear from the following extract that at least fifteen years earlier than the date named, and within ten years of the time when Scheele investigated the subject of the action of light on the salts of silver, the possibility of utilising the action of light was known. The title of the book from which the extract is taken is "Rational Recreations in Natural Philosophy," &c., by W. Hooper, M.D., 1787; and the paragraph is headed "How to print letters by sunlight."

"Dissolve chalk in aqua fortis to the consistence of milk, and add to that a strong dissolution of silver. Keep this liquor in a glass decanter well stopped, then cut out from a paper the letters you would have appear and paste the paper on the decanter, which you are to place in the sun in such a manner that its rays may pass through the places cut out of the paper and fall on the surface of the liquor. The part of the glass through which the rays pass will turn black, while that under the paper will remain white. You must observe not to move the bottle during the time of the operation."

Mr. Coote exhibited some snow scenes, the negatives of which were taken on collodio-albumen plates. Some of these beautiful views were slightly defective in the high lights, a number of vein-like markings appearing in the sky and foreground.

Mr. Wardley stated that these defects were entirely caused in the development, and had no connexion with the character of the collodion used, or with the preparation of the plate. He considered that the imperfections were produced entirely by the repellent or nonmiscible nature of the solutions, containing acids and salts, used in development, acetic acid being one of the chief causes of the defects. Another source of the evil may be a low temperature and the developing solution being allowed to rest, even for a moment, on the plate. Such defects may be produced in abundance on any kind of dry plate if the developing solution is allowed to rest.

ROYAL INSTITUTION.

Tuesday, May 14, 1867.

*A Course of Four Lectures on Spectrum Analysis with its Applications to Astronomy,** by William Allen Miller, *M.D., LL.D., Treasurer and V.P.R.S., Professor of Chemistry, King's College, London.*

Lecture I.

Nature of the Prismatic Spectrum.—Spectra of Solids.—Spectra of Gases and Vapours.—Spectra produced by Absorption.—Spectra of Rays of Heat, of Light, and of Chemical Action.

My object in the course of lectures upon which we enter to-day will be to endeavour to place before you distinctly the mode in which, by the optical analysis of light from various sources, we have learned not only to distinguish the physical condition of the body which emits that light, but also, in many cases, to ascertain its composition.

A new method of investigation is thus placed in our hands. The mode of analysis, it is true, has been practised before to a certain extent, but it involves the application of principles which, until quite recently, had been overlooked. It enables us to deal with matter at infinite distances, for, provided we can see it, we are able to examine it by this optical method. It also enables us to examine matter in quantities so minute that no balance can estimate its amount. We are therefore brought face to face, by its means, with infinitude of space and distance, and infinitude of minuteness.

I know that those who have been in the habit of attending lectures at this Institution have from time to time watched with interest the progress of this new branch of investigation. They have had opportunities from time to time of seeing the steps by which it has been raised to its present position, illustrated and experimented on; but although many who may be honouring me with their attendance on this occasion may not for the first time be considering these wonderful phenomena, the intrinsic interest which they possess—the variety and beauty of experimental illustration of which they admit—induce me to hope that even those who are in some measure familiar with the facts will yet be able to follow me with interest through the theoretical considerations which I may have to bring before them, and through the somewhat minute detail upon which, from time to time, I shall have to enter.

Without further preface, then, let me proceed to the examination of the method of inquiry—the method of optical analysis.

No doubt every one present knows what is meant by the prismatic spectrum. If we take a beam of white light, and transmit it through a triangular mass of glass properly cut and polished, we divert it from its original direction—we refract it from its course. Now, light may be artificially produced in various ways, and one of the most general of these modes of obtaining light consists in raising the temperature of the body which is to be experimented upon. Every opaque solid object gives out light in large quantity when its temperature is sufficiently raised. At a temperature of about a thousand degrees of Fahrenheit every substance becomes what is called red-hot—that is to say, begins to emit red light. As we raise the temperature, the colour of the light becomes more brilliant, and it passes at length into a dazzling white. That is a general effect whenever any solid opaque substance is sufficiently heated. I shall take advantage of this fact in order to be able to produce the beam of light upon which we shall have to experiment in a part of this investigation, and for this purpose it will be my desire to show you, first of all, the solid body itself which is

---

* Reported specially for this paper, and revised by the author.

producing the light, because, hereafter, I shall have to show you other sources of light which are not solid, and which are giving out light of a different kind.

In the first place, then, I shall, by the powerful heat produced by the current of electricity of the voltaic battery, cause intense ignition of two points of charcoal. You will excuse me if from time to time in these lectures I bring before you what appear to be very simple experiments. Philosophically, nothing is trifling if it proves a principle. In this case I shall throw upon the screen the image of two charcoal points. My object here is simply that you may see that although we get an intense light and a white light, it is produced by a body in the solid state. The charcoal points do not melt, and there is no visible vapour given off. I do not say there is no vapour given off, but there is none visible. On throwing this image upon the screen, we shall see, first of all, the incandescent points themselves, separated from each other to a considerable distance. Having shown you the points, we will then examine optically the nature of the light which those points are emitting.

You will observe that the image of the line of light is produced by allowing simply a thin slice of light to pass through a very narrow slit. It is now falling upon the surface of a mirror, and from that mirror it is reflected upon the screen. We will now withdraw the mirror altogether, and allow the light to pass through the prisms which have been arranged for its dispersion. So long as these points of ignited matter are in the solid condition, we have that beautiful elongated image which now appears upon the screen, and which is, in fact, composed of a series of slices of light, each of which is of a particular and definite colour. You will notice that the extremity which is nearest to me—the red—is that which is least refracted from the original direction, and the extremity which is farthest from me—the violet—is that which is most refracted from the original direction. Now, the point I particularly wish to insist upon in this observation is that we are here dealing with a *solid* body, which is not capable of being converted into vapour so as to produce flame. If time allowed, I should like to show that this, which is observed in the case of charcoal, is a general fact with regard to solid bodies. For example, if, instead of heating charcoal points by the voltaic current, I were to take a cylinder of lime and introduce it into the intense heat of the oxyhydrogen jet, or if I were to take a piece of magnesium, a piece of silica, a mass of iron, or a mass of platinum, and heat it so as to produce incandescence or intense ignition, the spectrum which would be obtained from its light, would, in every case, when examined, be seen to be continuous, like that charcoal spectrum. [I dare say you noticed flashes of light which crossed that spectrum from time to time. They were due to slight impurities in the charcoal points, and these impurities become volatilised in the intense heat. With them we shall have presently to deal.] The particular fact upon which I wish now to insist is that, as a general rule, whenever a solid body is heated, it gives out light, which, when examined by the prism, furnishes us with a continuous spectrum. That is to say, this light is made up of an infinite number of slices of light. By means of a rough model, I may make this more clear. Suppose that this white bar represents to us a band of white light—the light, in fact, which we first got before it is dispersed by the prism. If we cause it to pass through the prism, it is spread out in this fan-like manner, every piece of that spectrum being composed of a slice of light of the particular colour which is there represented; and these slices of light, overlapping each other continuously, produce that blending of colour which is inimitable by art, but which is so brilliant and so beautiful in its effect.

These, then, are the results of the examination of bodies in the solid condition, and for the purpose of recalling this to your mind we have here a diagram representing the spectrum of any sufficiently luminous solid body. And, further, if the solid happens to melt, it still gives out a continuous spectrum. A mass of melted cast-iron, for instance, would furnish a continuous spectrum, as in the case of charcoal. Or if we were to take any other metal which can be heated sufficiently to be melted without boiling and volatilising, we should obtain a similar result. I cannot show you this experiment, because I am not able by means of the voltaic battery sufficiently to regulate the heat.

Here let me notice that in spectra of this kind we have no clue to the chemical nature of the body which produces the spectrum. But if we go a step further, and heat the body sufficiently to convert it into vapour, the spectrum which is then obtained is quite of a different nature. Instead of having a continuous spectrum, we shall have an interrupted spectrum; and I am going now to prove to you that the body upon which I am experimenting is converted into vapour before it furnishes a spectrum, and for this purpose shall introduce into the lamp a charcoal cup, upon which we shall place a piece of silver. That silver will immediately melt with the intense heat of the current, and as the current is continued, it will not merely melt, but it will actually boil, and become distilled. In fact, silver has been distilled on a large scale by Stas, for the purpose of its purification. [The image of the charcoal points on which the silver was placed, was thrown on the screen.] That beautiful green arc is the vapour of silver. The silver, you will remember, appears on the upper part of the screen, in consequence of the inversion of the image. What in the lamp is the lower part is here upon the screen the upper part. You will see a number of little glowing points, which are the distilled silver. Well, now, if we could manage to open out these glowing points of melted silver (but which we cannot in the present form of our experiment), we should see that they were giving out light of all colours, but the arc itself is giving out light of a particular colour.

We shall now examine the mode of discriminating between silver and other bodies, by means of this process of optical analysis. In another lamp I have exactly the same arrangement as that which you have here seen thrown upon the screen; but, instead of making the image of the points fall directly upon the screen, I shall let a slice of light only fall upon a lens in front of the slit, and then upon a prism. Now, you will notice that the instant the temperature rises sufficiently we get these two magnificent green bands. These two bands are the characteristic marks of silver in vapour. They constitute the arc of light which we saw just now upon the screen, and which is here, by means of the prism, spread into its component parts. You will notice that there is on the ground of these bands a small amount of light, which is due to the dispersion of the light from the charcoal points. We cannot avoid that. In these cases we do not get the pure light of the substance upon the points, because the heat which is produced is sufficient to give us a tolerably strong spectrum of the charcoal points. But you will observe how very much those green lines predominate over the other light in that spectrum.

The next fact which I have to bring before you is that though every substance which is capable of being converted into vapour gives a spectrum, it gives a spectrum *of its own*. If you take substances which to the naked eye appear to possess exactly the same colour, the moment you place them in the voltaic arc the vapour given out by each is capable of being distinguished from the others, and you have a different spectrum for each body. I will illustrate this by means of four different bodies, each giving a green light. I have shown you the spectrum of silver. Now I will take three other bodies, each giving a green light, differing a little in its shade from that of the others. The first of these will be metallic copper, which, like other metals, will boil in the intense heat we can here produce. The vapour of copper will give us a spectrum of its own, which, although green, will not be the same as the spectrum of silver. [The spectrum was shown on the screen.] There you see a series of green bands, but in the case of copper there is also a large quantity of red and orange light. You see a series of channeled or grooved spaces through a pale background, due to the light from the charcoal points themselves; but the brilliant portion of the spectrum is produced by the volatilisation of the metal. You will be able readily to contrast this copper spectrum with the spectrum of the silver which we had before. Here, you observe, we have a green, but a green of a different order. Copper is a more fixed metal than silver, but by means of this intense heat it becomes converted into vapour. Solid copper, if heated, would not give us this line, but a continuous spectrum like lime and like charcoal.

I am now going to take another metal, which also gives us a green light, and I have a special reason for selecting this metal—magnesium—because we shall consider it from another point of view hereafter. Magnesium is a metal which, when burned with proper precautions, gives rise to a beautiful green light. I dare say we shall see some blue also, but the principal part of the magnesium spectrum will be a green light, but a green of a different shade from the others. In this case you will not see the fact that the green light of magnesium is concentrated into three bands. These three bands are so exceedingly close together that the apparatus we have at our disposal for throwing them on the screen does not enable us to separate them. In this spectrum of magnesium you will see a certain blue line, and there is also a faint line nearer to the yellow.

The fourth metal which I have selected also gives a green light, and this is likewise an extremely interesting body. It is thallium, a metal which was discovered by the application of the method of spectrum analysis. [The spectrum was produced.] That is the band which is perfectly characteristic of thallium. Whenever we have pure thallium we have that single intense green line.

From these experiments it is obvious at any rate that these four substances have totally distinct spectra, although the light which these metals emit appears similar when viewed with the prism. If we were to throw slices of their light directly upon the screen, we should not be able to distinguish these metals from one another; yet, by spreading them out in this fan-like form by prismatic analysis, it is easy to distinguish one from the other.

We have then here a second set of spectra, and these spectra are such as are represented in the second of our diagrams. They are spectra which are not continuous—interrupted spectra—spectra with bright lines. These occur in the case of flames and ignited vapours and gases. It is true that in one instance a solid body has been known to give out lines like this, but it is a substance which I suppose not a dozen people have ever seen. Still it is an important fact that the metal erbium, in the form of its oxide erbia, even in the solid, has the power of giving out bright lines when its spectrum is viewed. This is an awkward fact for the theory of spectrum analysis, but at the same time it is one which must not be ignored. We are always discovering facts which do not square with our theories; and the more these facts are examined, the more surely are we led on to correct our theories, formed, as they always necessarily are, from partial knowledge only. This exception in the case of erbium does not, however, invalidate the general conclusion that whenever we see a body which emits a spectrum having bright lines, that body is in a gaseous condition. We do not as yet know why erbium makes an exception, though at some future time, probably, we shall be able to account for the apparent anomaly, the discovery of which we owe to the observations of Bunsen, to whom also we are indebted for a great part of our knowledge of spectral phenomena.

We must now turn our attention to the cause of these remarkable phenomena; and here I must ask you to follow me for a few moments through a little speculation—not that it is new, but it is speculation which is necessary to connect our ideas—speculation as to what light is. The notion of the nature of light which is at present adopted by philosophers is of this kind:—Filling all space, and filling the interstices of all kinds of matter, there is a subtle something which, for want of a better name, is called "ether." This ether has no weight. It is not light itself, although it is the means by which light is manifested to us. (Mind, this is all speculation, but still it is necessary.) When this ether is thrown into vibration, the vibrations are transmitted through space in right lines, radiating in all directions from the point at which the vibration is produced. When these vibrations have a certain degree of frequency, they produce the phenomena of radiant heat; when they have a somewhat greater frequency, they produce phenomena which are manifested to us in the shape of light; and when these vibrations are more frequent still, they produce phenomena which are manifested to us in chemical effects, or in those effects which Professor Stokes has taught us to associate with the term "fluorescence." Now, the different degrees of frequency with which the ether can be made to vibrate give rise to certain phenomena in light. Not merely is light a vibration of one particular frequency, but the different kinds of light are produced by vibrations differing in the degree of their frequency. Those portions of light which are least refracted (the red) are produced by vibrations of the ether of the lowest frequency; those portions which are most refracted (the violet) are produced by vibrations which are of the greatest frequency; and intermediate between these we have vibrations which produce all the intermediate colours. Now, although it is true every one here is prepared to hear wonderful statements of this kind, I was going to say I scarcely dare to mention the number of these vibrations which it is calculated must occur. Let me first tell you what the width of a wave of light must be. Every wave of this ether, as I have stated, is liable to vary in width according to the colour of the light. In red light the width of a wave is about the 34,000th part of an inch. A wave of violet light is a little more than the 60,000th of an inch—that is to say, there would be a series of 60,000 of these little waves in the space of an inch. That seems a tolerable number, but when we come to the frequency with which these undulations succeed each other, it is perfectly marvellous. In red light there are 482 millions of millions in a second of time, and there are upwards of 707 millions of millions in the case of violet; and we may fill up the interval of the intermediate colours with every conceivable variety between the two.

Now, it is very difficult, when one is looking at these things for the first time—and, indeed, it is always difficult—really to grasp these things, and therefore it is needful that we should come down to something a little more within our ordinary range of conception. I shall, therefore, take an illustration or two from another set of vibrations which you had most admirably illustrated not long since by Professor Tyndall. I cannot help reminding you of one or two beautiful experiments which he brought before you, and which show the beautiful analogy between colour and sound, for, in point of fact, red is the bass of light, and violet the treble. You all know that musical notes are produced by a certain series of vibrations which occur in definite number and at perfectly regular intervals, each note having its own specific number of vibrations—the middle C, for instance, in a pianoforte, having 256 vibrations in a second. C in the octave above has double that number, or 512. Here is a tuning-fork which will give us a note which will cause the air in this box to vibrate. [The fork was struck, and held over the mouth of the box, whereon a musical note was obtained]. This fork is producing a certain number of vibrations, which vibrations correspond to a column of air of a particular length contained in the box. Now, if I take another of these forks and hold it over the next box, we get a note which is the octave above. [Experiment performed.] There are twice the number of vibrations in that sound as there were in the sound which I produced first. In the case of musical notes we have a series of these sounds succeeding each other in order. Now we take another fork, and hold it over the next box; then, again, the next; and then the last, this being the highest of all. [A musical sound was evoked in each case, each successive note being higher than the preceding.] Now, these are, in point of fact, to sound what colours are to light. In the case of light, we cannot get through the octave. If we assume that the proportion of vibrations in red light be 100, those for the violet light will not exceed 175; so that the number of vibrations, immense as it is in the case of light, does not embrace so wide a range as in the case of sound, for we may have musical vibrations ranging from 16 in a second to upwards of 2000 in a second.

I have no doubt that many of you know the beautiful experiment which I first saw performed by Dr. Tyndall here, and it is so beautiful that I cannot help desiring to show it to you again, although I may not succeed so well as he does, because it is a matter which he has made his own. The experiment is this:—If we take two tuning-forks, one of them an octave above the other, and each having a thin wire attached to the limb of the fork, and cause them to vibrate, and if we then draw them at the same rate across a piece of smoked glass, we shall have a sinuous line, which will represent the motions of each fork. [A piece of smoked glass was marked as described.] We will put this into the lantern, and you will see on the screen two sinuous lines, one above the other. The lower line is that which is produced by the bass sound; the upper one is that which is produced by the higher sound. The sinuosities in the upper line are double the number of those in the line below. In this we have ocular proof of the difference between the rate of vibration of the two forks. If we were to rule lines across, we should find that the bends in one of these lines were twice as numerous as in the other. This is one of the simplest and, at the same time, the readiest proofs we can have of the difference in the vibrations.

Now I must ask your attention to a third set of spectra. We produced, first of all, a continuous bright spectrum, then an interrupted bright spectrum; but what would happen if we interposed between a continuous spectrum and the light something which would take part of the light away? If we put an opaque body, we should arrest the whole of the light; but if we introduce a transparent coloured substance, we shall intercept portions of the light. Now, by properly choosing our media, we may produce interrupted spectra with black or dark lines upon them; and these are spectra of a high degree of interest. I shall exhibit one or two of the methods by which we may produce these effects. When light is transmitted through a solution of permanganate of potash without using the prism, the liquid has a splendid purple or red colour, according to the degree of dilution. We will first show the spectrum of white light, and then we will interpose the permanganate. You will see, when this solution is placed in a glass cell with flat sides, so as to intercept the spectrum from the charcoal points, we obtain a certain number of bands, which occur at intervals upon the screen.

I now proceed to the examination of one of the salts of the rare metal called didymium. Nitrate of didymium and potash furnishes a solution of a very pale red colour. When this is introduced in the course of the ray you see two remarkable bands, one in the orange and the other in the green. Besides this, portions of the blue rays are also cut off. This is a spectrum of absorption produced by a liquid which has so faint a colour that it is scarcely perceptible to the naked eye, yet its spectrum is perfectly characteristic. Dr. Gladstone, who first pointed out this peculiarity of didymium, was enabled by its means to discover didymium as an impurity in other bodies previously supposed to be free from it. These two last spectra, you will observe, are absorption spectra produced by liquids. Such absorbent actions are important, as they enable us in many cases to distinguish the nature of the bodies which are held in solution. Professor Stokes has insisted particularly upon the value of studying this class of actions; and quite recently a valuable paper upon the subject has been communicated to the Royal Society by Mr. Sorby. But, interesting and important as this branch of inquiry is, it would lead us too far astray from our immediate subject, which is specially concerned with the examination of the spectra of bodies at a very high temperature, and the action upon such spectra of gaseous bodies, either at ordinary or at elevated temperatures. The phenomena with which we have at present to deal, enable us to examine the constituents of the gases in furnaces, in active volcanoes, in the fixed stars, in meteors, and in those still more enigmatical bodies, the nebulæ.

For this purpose we will now examine the absorbent action of a brownish-green coloured gas, the peroxide of chlorine. You see there are bands coming out, there being an absorption, particularly of the blue and violet portion of the spectrum, to a very considerable extent. The bands are still more marked in those portions of the spectrum which are not visible until they are received upon a fluorescent screen. The next gas which we will introduce in the same manner, interposing it exactly in the track of the ray, is the peroxide of nitrogen (the red nitrous fumes which are produced whenever a metal, such as copper or mercury, is acted upon by nitric acid). The bands in this gas are in a different portion of the spectrum. The green is almost abolished, and in the green and orange we have a variety of dark bands appearing. These bands are of particular interest because they were the first absorption bands which were observed. Sir David Brewster, who discovered them, thought that he saw in them a clue to the explanation of certain bands known as Fraünhofer's lines which are observed in the sun's light. This turned out to be only a partial foreshadowing of the truth, but still the fact is interesting in the history of these discoveries.

I have now shown you absorption by two coloured gases, both of them, however, at the temperature of the air. Suppose we now take a substance which is highly heated, and then examine what will be the effect of transmitting light through a vapour of this description. For this purpose I will now place in the lamp a substance which gives a light of one colour only. Sodium, when converted into vapour, gives out light concentrated into two extremely narrow bands, very close together; these are actual mathematical lines of light which cross the spectrum in the midst of the yellow. I cannot show you these lines on the screen, for the form of the apparatus is not calculated for the production of these extremely sharp lines. As the temperature rises, the sodium becomes converted into vapour, and it will gradually become more and more brilliant until you will see that this bright line is crossed by an intense black line, showing itself upon the screen in the position which was, a few moments ago, occupied by the sodium line itself. It flickers for an instant, and then it gradually fades. Again it appears, and you may now see distinctly the black line of the sodium thrown upon the screen. That is an experiment which, simple as it looks, is really the foundation of the whole, and therefore it is that I have taken a little more time than usual in obtaining the result. I need not apologise to you, I am sure. You are accustomed to look at these things, and to value them, not for the brilliancy of their appearance, but for their real importance with regard to the subject in hand. Now, this sodium light has, as you will observe, the power of causing a black absorption band, when light, produced at a very intense temperature, is allowed to fall upon the incandescent vapour or flame of the metal at a lower temperature. Those are the conditions under which the absorption band is seen, and the person who first pointed out the real significance of the fact was Kirchhoff. The actual fact was first observed and described by Foucault, and Mr. Stokes suggested an explanation, which turned out to be the true one; but although he divined it, he did not directly prove it by experiment, or publish it to the world, and so make it his own. Kirchhoff, however, not only saw that this sodium vapour absorbed the light of the luminous body behind it, but that in this fact lay the explanation of those remarkable dark lines in the sun's light, which ever since they were first indicated by Wollaston, and carefully examined by

Fraünhofer have been a mystery to all philosophers. The black lines of Fraünhofer are represented in this diagram, which is a repetition of the upper spectrum, *plus* a certain number of black lines which cross it at intervals. The black sodium line has a corresponding black line in the solar spectrum exactly at that part which is marked D. I say "*a* black line." It does, in fact, consist of two lines, which can be discriminated from each other by the use of telescopes of sufficient power.

Now, I desire, if I can, in a few words, to explain to you how this black line is produced. It certainly seems a remarkable thing that the addition of two lights should apparently produce darkness. We know this, however, for a fact in other cases; for light, and in some cases sound, produces the phenomenon of interference, as it is called; but this is not a true case of interference—it is a case of absorption. The spectrum of sodium has the power of absorbing only that thin line of light which it made upon the screen, just as, when we take one of these forks and hold it over the particular box which responds to it, and which absorbs its vibrations, it produces a sound; but the fork produces no sound when held over a second box of different dimensions [holding it over another box]. In the first case, we have a powerful resonance, but there is nothing perceptible from either of these other boxes. Well, this furnishes us an analogy—though a rough one—to the way in which the sodium vapour acts in taking up the vibrations which are produced in that particular slice of light from the sodium, appropriating them to the actual raising of its own temperature, and then radiating them out—wholly absorbing them first, and then reradiating them.

How is it that this is a black line? In the black line, as it appears upon the screen, it is true that there is a greater amount of light than the sodium alone could produce, and it is black only by contrast. That part of the spectrum which looked black just now would have appeared bright if seen alone, but as I had a more brilliant spectrum behind it, the light of that spectrum, in falling on the screen, produced upon the eye the effect of a contrast, which led you to believe that the comparatively feebly illuminated sodium line was actually black. That is the cause of the black lines we appear to see in the spectrum of the sun, of the fixed stars, and of a variety of other lights.

I intended to say a word or two upon the composite nature of the solar spectrum before I concluded this part of our subject; but I need not dwell long upon this point, as it has already been insisted upon more than once in the theatre of this Institution. I stated just now that if we obtained the solar spectrum, and examined it—spread it out—we should have a certain amount of light, which we may represent by that band of coloured light which is seen in this diagram. If you notice, you will observe that that coloured stripe is bounded by a curved line above. This is the red end, and here it goes off into the violet. Now, this curve is the result of measurements made very carefully by Fraünhofer for the purpose of ascertaining what is the distribution of light in the different parts of the solar spectrum. A second curve traces the outline of this black mountain, which Dr. Tyndall has been working at, and is intended to indicate the distribution of heat in the spectrum. It is very important to remember that the light given by the sun is but a small portion of the force which it is radiating upon the earth. The portion of the curve filled up with black represents that part where the vibrations are least rapid. Then, when the vibrations increase in rapidity, we get red light. Still more rapid vibrations give us yellow; still more rapid give us green; then we get to the blue and violet. The principal curve in the diagram represents to the eye very roughly, but to a certain extent correctly, the distribution of heat in the visible portion of the spectrum. The heat increases in intensity as we approach to the red, and the light diminishes. The third curve represents the distribution of the chemical rays. If you allow the spectrum from the light of the electric spark taken between points of silver to fall upon the photographic surface of a collodion film, you get a very long strip of light, in which you have a series of the same sort of bands as you have already seen in the luminous portion of the silver spectrum. The vapour of silver gives us a series of interrupted bands, which exert a powerful effect in photographic experiments.

One experiment before I conclude, in order that I may show you the photographic image of the spectra obtained by transmitting a series of powerful electric discharges between wires of the four metals which I spoke of just now. First, the spectrum of silver. There you will see the image prolonged. This is the most refrangible part. The photographic image of the electric spark between wires of silver is five or six times as long as the visible spectrum obtained from silver when heated in the voltaic arc. Here is the photographic spectrum of magnesium, and here is a photograph of the spectrum of thallium. About one-tenth only of the length of any of these spectra is visible to the eye. Finally, here is the photographic spectrum of copper.

PHARMACEUTICAL SOCIETY.

Wednesday, May 15, 1867.

G. W. Sanford, *Esq., President, in the Chair.*

The twenty-sixth annual general meeting of this Society was held on Wednesday, the 15th inst., when the report of the Council was received, and the Council and Audit Committee for the ensuing year were elected. The meeting then resolved itself into a special general meeting, convened for the purpose of taking the sense of the members of the Society relative to the 19th clause in the amended Pharmacy Act. This was one of the largest meetings of members ever held. Mr. Abrahams, of Liverpool, moved, and Mr. Boyce, of Chertsey, seconded, a resolution condemning the policy of applying for an amended Act when the Society was in such a prosperous state. Messrs. Pedlar, Richardson, and others thought that by admitting all chemists without examination they would be doing an injury to those members who had already passed the examinations. After a long discussion, Mr. Collins, of St. Pancras, moved, and Mr. E. Vizer, of Pimlico, seconded, the following amendment:—"That, in the opinion of this meeting, the proposed amendment of the Pharmacy Act is both wise and expedient, as, by enlisting the support of those members of the trade outside the pale of the Society, the way is cleared for carrying into effect the primary objects of the Society—viz., the consolidation of the whole trade, and legislative provision for the compulsory examination of all persons entering the same after a given time. This meeting would further express its entire approval of the action taken by the Council, and pledges itself to support, by all possible means, the passage of the Bill through Parliament." Messrs. Edwards, Squire, Orridge, Morson, Savage, and Randall supported the amendment, which, after considerable discussion, was carried by a large majority.

ACADEMY OF SCIENCES.

April 29, 1867.

(From our own Correspondent)

The sitting of the Academy was very short to-day.

Sir David Brewster presented the opening discourse which he had made at the Edinburgh Royal Society.

M. Baer, of St. Petersburg, warmly thanked the Academy for having given him the Cuvier prize of 1866.

M. Baumhein, present at the meeting, called the attention of a considerable number of members, particularly M. Fizeau, to a forgetfulness on the part of the commission appointed to award the prize for the determination of the length of the waves of the solar spectrum. He deeply regretted that they had not known the remarkable memoir of M. van der Willigen, director of the Teyler Physical Cabinet at Haarlem, which was more complete than that of M. Mascart in 1866.

M. Dumas read a letter, in which M. Pasteur, at present at Alais, and who is finishing his experiments and observations on the precocious rearing of silkworms, announced an important discovery made by him. The organisms that he terms *corpuscles* are propagated, or at least multiplied, by *scissiparity*. They contain a sort of kernel, which ordinarily presents the first indications of scissiparity. M. Pasteur has examined under the microscope the corpuscles of the internal mucous coats of the stomach and the kernels, at all states of division, commencing, in progress, or terminated.

M. Dumas, in the name of M. Naquet, presented the second edition, in two volumes, of his "Principles of Chemistry founded on Modern Theories." It is a well-written work, quite up to the modern progress of science. M. Dumas, however, reproaches the author with having regarded facts too much in a personal light, and enumerating the results without mentioning the processes. Formerly, said the celebrated chemist, the processes were an important item in the teaching of chemistry; and also he has further remarks to make on this reserve, which he will make on a future occasion.

M. Fremy presented a memoir on "*Phenol*," in which M. Dussard announced that he had succeeded in perfectly and easily producing the phenaphtic acid of Berzelius, and preparing diatomic phenol possessing very remarkable properties, and which will bear the same relation to the monatomic phenol as the glycol of M. Wurtz bears to monatomic alcohols.

M. Henri Sainte-Claire Deville presented a note, by M. Cailletet, on an amalgam of sodium with which he has already obtained considerable success. He called to mind the important results obtained by the modern researches of Messrs. Crookes, Matthiessen, Regnault, &c., on alloys. Mr. Crookes, for example, had rendered great service to metallurgical operations by proving that the addition to mercury of a small quantity of sodium renders incomparably more easy and profitable the extraction of the precious metals.

Mr. Sterry Hunt read the summary of his researches upon certain reactions of magnesian salts and magnesian rocks. The author attacked the theory of MM. Haidinger and Suckow, who explain the efflorescence of sulphate of magnesia by the reaction of sulphate of lime and carbonate of magnesia. He believes that the magnesian silicates which form portion of the dolomites in the environs of Paris are the representatives of the unaltered formation of steatites; that the talcs and serpentines are formed aqueously; that the greensands of the Paris basin are of the same composition as serpentines, &c.

May 7, 1867.

M. Bertrand read a very favourable report on the memoir of M. A. Cornu, entitled, "*Théorie Nouvelle de la Réfraction Crystalline de Fresnel.*" The principal conclusions of the report were, that the luminous vibrations were normal to the plane of polarisation, as Fresnel and Cauchy announced a long time ago, though the direct proofs hitherto proposed are open to discussion.

M. Charles Robin resumed the result of his researches on the origin, development, and completion of the dorsal cord, called the cord of Owen.

The Academy proceeded to the election of a Correspondent for the Geometrical Section in place of M. Rieman. The choice almost unanimously fell upon M. Plucker, of Bonn, the well-known Professor. He received the Copley Medal of the Royal Society for 1866, and many honours which we cannot now enumerate.

M. Salmon, of Dublin, author of "Lessons in High Algebra," &c., obtained the vote left by M. Plucker.

The Academy then proceeded to the election of an Anatomical and Zoological Correspondent. M. Siebold, brother of the Japanese traveller, was elected by a large majority.

M. Balard presented an ice-making machine, made by M. E. Carré, brother of the well-known inventor of the ammonia one. Its action depends on the absorption of vapour of water by sulphuric acid, and the congelation is most rapid, as soon as the vacuum is produced.

M. Regnault, in the name of M. Soret, of Geneva, communicated a new note on the determination of the density of ozone. Experiments of absorption lead to the conclusion that the density of ozone is one and a half times that of oxygen. He applied Graham's law of diffusion—viz., that the diffusion takes place in the inverse proportion of the square of the density. He then diffused two mixtures—one of oxygen and chlorine, the other of oxygen and ozone. Thus compared, the density of ozone to that of chlorine or oxygen was found to be 1 : 5.

May 13, 1867.

(From our Special Correspondent.)

Dr. Nelaton begged the Academy to inscribe his name among the list of candidates for the vacant chair in the medical and surgical section, by the death of M. Jobert de Lamballe. Is he not rather late in the field—when, during all his life, he was no more interested in the Academy than if it never existed; and when he never made his appearance but once, to read a work made in collaboration with a young recruit? He must have depended upon the little respect paid by the Academy, sometimes, to itself, to offer himself as a candidate in such an unprepared manner. For my part, I shall not give my vote to M. Nelaton, first-rate surgeon though he be among us.

M. Boussingault communicated a new series of researches relative to the deleterious influence exerted by the vapour of mercury on the vitality of plants. He has repeated and modified the very curious experiments made by some Dutch *savants* in 1797. They placed under a bell glass a plant, with a small vessel containing mercury, and they found that, at the end of a few days, or even a few hours, the leaves of the plant were spotted and blackened, and that it ultimately perished. But when they fixed a small piece of sulphur on the inside surface of the bell glass, the deleterious action of the mercury ceased, and the plant remained healthy. It was not difficult for M. Boussingault to assure himself, by a series of careful observations, that the mercurial vapours had a sort of elective affinity for the sulphur—that sulphuret of mercury was formed, which is inoffensive. M. Boussingault has varied his experiments relative to the action of vapours on plants and the precious metals, silver and gold. He has measured their tension, and appreciated their action on the colours and weight, &c. M. Regnault thinks that the best reagent against the vapours of mercury is an iodised daguerreotype plate ready to be coated and exposed to the light. M. Boussingault maintains that the sensibility of the plates is nothing as compared with that of plants.

M. Pietie, of Geneva, was then elected as member of the Section of Anatomy and Physiology, by forty-two votes against one, given to M. Sace, of Neufchatel.

M. Becquerel, the elder, communicated his series of experiments on the influence of the capillary action of surfaces upon decomposition and chemical combination. He takes a tube with two branches reversed, and makes in it a fissure, the width of which is infinitely small. He pours therein a solution of nitrate of copper, and has found that no liquid passes by the fissure; but when placed in a vessel containing liquid protosulphuret of sodium, an electrical action takes place, and decomposition and recomposition ensue, manifested by the crystals which appear on both sides of the fissure. M. Becquerel has demonstrated the new and curious phenomenon that the capillarity of the fissure has a real influence on the nature of the products of the decomposition; that the salts or the crystallisations are not always those indicated by theory; that the double decomposition often goes to the extent of reduction of the metal.

M. Elie de Beaumont presented, in the name of M. Civiale, an immense collection of urinary calculi, arranged according to their form and structure, composition, &c. He read a long note, giving details of each group.

M. Ch. Sainte-Claire Deville recounted his studies "*On the Periodical Variations of Temperature.*"

The author has established, in one of his former memoirs, that there exists a certain depending connexion in the movement of the mean temperature of four days, placed on the ecliptic at an angle of 90° one from the other, for the four months, opposed two by two, of February, May, August, and November, which contain the critical days, known by the ancients under the name of the *three saints of ice* (May 11, 12, 13), and the *summer of Saint Martin* (November 11). In this new work he shows that the fact is general, and that this connexion or mutual dependence of the four opposite days exists during the whole of the year; whether we take into consideration a considerable cycle—110 years at Berlin, 90 years at Vienna, 50 at London, 40 at Prague and Edinburgh, 30 at Brussels, 24 at Toulouse, 21 at Paris — or that we take in this point of view an isolated year (1864) on several European stations.

The former, depending upon the same data, establishes, in fine, that this connexion is evident also when we combine twelve by twelve the days separated one from the other by 30° of the ecliptic.

The latter phenomenon constitutes the *meteorological month*, as the *season* was established by the consideration of the quadruple days.

M. Marié-Davy presented his ninth memoir "*On the Mechanical Theory of Electricity*." The *résumé* that we shall shortly publish is a sort of synthesis of the principal phenomena of nature. These are his conclusions:—In a ray of light the vibrations are not in the direction of the wave. In a hot substance, in which μ varies symmetrically all round each material centre, the vibrations take place generally in the same manner on the three axes. In the circuit in activity the electric vibration takes place in the direction of the propagation of the current, and the *vis viva* set at liberty by the chemical action passes along that channel. But light, heat, and electricity have the same *vis viva*, having the same mechanical equivalent.

In this hypothesis of the vibrations, the positive electricity is ether condensed in excess; negative electricity is ether in deficiency. It is a long time ago that we sustained this theory, on which we made a memoir presented to the Academy in 1845. Baron Sequier, in the name of M. Stamm, of Milan, communicated the plan of an association between a horse and a steam motor, inspired by a lecture that he gave last year before the Academy, and in which he drew such a clear comparison between inanimate motors and animate ones working by their own will. M. Stamm, in his vehicle with a steam engine commanded by a horse, has so disposed it that the horse gears the machinery when in motion, and ungears it when he stops; so that he arranges the valves in a manner that, when backing, the steam is reversed, and the intelligence which the machinery wants is supplied by the horse.

May 20, 1867.

M. **Delaunay** presented, in the name of M. Camille Flammarion, a note on a change remarked on the surface of the moon in the crater of Linnæus. It is well known that this crater has recently been subjected to an essential modification. The attention of astronomers having been called to this fact by M. Jules Schmidt, of Athens, M. Flammarion chose the moment when the sun rises at the meridian of Linnæus to study this spot. The sun, being only yet elevated a few degrees above the horizon of the crater in question, lit it up very obliquely. The slightest irregularities in the conformation of the surface were most distinctly visible. An attentive observer would remark at once that Linnæus is no more a crater; there is no exterior shadow, no shade in the centre. In its place there is only a cloudy, white, circular spot, or rather a white stain on the ground. Far from being elevated as a crater, it has a greenish color, like the Sea of Serenity, and seems to be neither in relief nor sunken, but resembles a lake of a lighter colour than the neighbouring plain.

This crater has therefore descended to the level of the plain—fallen in—or else the plain has been raised to about the level of the crater. The interior appears also filled up, for no shadow is distinguishable, whilst smaller craters, such as A and B of Bessel, A and B of Linnæus, and those in the neighbourhood of Posidonius, show the dark shadow very perceptibly. If Linnæus had this aspect at the time when Beer and Maedler laid down their selenographic map, it would have been impossible to have indicated it as a crater. In the map constructed eight years ago by Lecouturier the height is not marked. It appears that it was very deep, ten kilometres in diameter, and that it served as a fixed point for Lorkmann and Maedler.

On May 11, the sun being more elevated, Linnæus presented the same aspect as on the evening before. The evening of the 12th was rainy; the 13th the atmosphere, being very pure, permitted the author to distinguish in the Sea of Serenity a multitude of small disseminated craters. The plain was brilliant, and Linnæus had the same relative brightness.

M. Chacornac, who observed the same things at Lyons, arrived at similar conclusions. Father Secchi, of Rome, has already presented to the Academy his own observations. It is, then, proved for a certainty that a movement has recently taken place in this region of the lunar world. The magnifying power used was 230 to 300 times.

Baron von Liebig read a note "*On an Alimentary Preparation for Replacing Human Milk for Children.*" Human milk of a person in good health contains, per cent., caseine, 3·1; sugar of milk, 4·3; butter, 3·1. Baron von Liebig concluded therefrom that woman's milk contains:—Blood-forming principles, 1 part; heat-producing principles 3·8 parts. By mixing flour and milk in certain proportions, it is easy to compose a food in which the two nutritive principles are in the same proportion as in human milk—viz., 1 to 3·8. Cows' milk contains, on an average, 4 per cent. of caseine, 4·5 of lactose, 2·5 of butter. If we take, then, 10 parts of milk, 1 part of wheat flour, and 1 part of ground malt, we have a mixture satisfying all the necessary conditions. For preparing this the author recommends the following method:—A mixture is made of 15 grammes of wheaten flour, 15 grammes of ground malt, and 6 grammes of bicarbonate of potash; 30 grammes of water and 150 grammes of milk are then added. The whole is then heated and continually stirred until the mixture begins to thicken. It is then taken off the fire and stirred all the while. After five minutes it is boiled, and then strained through a wire or hair sieve. The ground malt necessary for this preparation is easily furnished by barley malt, obtained at any brewery. It can be ground in a common coffee-grinder, and then passed through a sieve. If this preparation is well made, it is as sweet as the natural milk; it is fluid enough, and keeps for twenty-four hours. In Germany the use of this food is very extensive, and its nutritive qualities are found to be excellent. It has a slight taste of flour or malt, to which children get accustomed—in fact, they soon prefer it to any other food.

M. Charles Robin presented on the part of the family of M. Godard, a work of this doctor entitled "Medical and Scientific Observations made in Egypt and Palestine." This *savant*, who died at Jaffa of a liver complaint contracted at Jerusalem, where he was studying leprosy, founded an annual prize of 1000 fr. already twice awarded by the Academy of Sciences.

M. Paul Thenard announced that M. Michel Perret by an ingenious process, the result of theory and practical studies, had made a great improvement in the art of making wine. He avoids at the same time acetification, and obtains better colour and more spirit.

This paper was followed by one on chemical researches on the water found in a bronze vase at Pompeii. On the 29th of March last, while making some excavations in a house at Pompeii, a bronze cooking-pot was found on an iron tripod. A cover, also of bronze, fitted exactly upon the top of the vase, so that water falling upon it could not penetrate into the interior. On the ground were found three handles, also of bronze, two of which belonged to the vase, and the other, formed of two dolphins, belonged to the cover. They had originally been soldered to the vase and cover. The vessel was found full of water. The diameter of the vase was 15 centimetres, and it was 20 centimetres high. The water was perfectly limpid, and was hardly rendered turbid by a prolonged ebullition with a feeble alkaline reaction. At the temperature of 20° C. its sp. gr. is 1·001, about that of distilled water. The quantity of fixed matters left by evaporation was 1·032 gr. per litre. The gases disengaged by ebullition consisted of air and carbonic acid. Lime and magnesia were found in it; also phosphates in small quantity; also some traces of sulphates, and even silica and iron. There was not the slightest trace of copper.

NOTICES OF BOOKS.

Discorso di Apertura del secondo anno della Facoltà di Chimica. Letto dal Fondatore, Prof. Carlo Cassola. Napoli. 1867.

The address of the President at the opening of the second year of a chemical college could hardly, our readers might say, contain much novelty, or any details which they could not note down beforehand. Of course he would give a general glance at the position of chemistry, the progress of discovery, and the prospects of the institution where the science was cultivated and taught. The above address does nothing of the kind. Italy has been too long under despotic rule to have retained her old courage for scientific inquiry, and now that she has happily reconquered liberty, she is only beginning to see the necessity of cultivating science as one of the most urgent means of cultivating the sources of national wealth. Hence this address is most curious and suggestive; its elementary character, its all but juvenile pretensions, have something of encouragement in them; so that in laying the substance of this discourse before our readers we are sure they will join us in an expression of sympathy for young Italy, and in the hope that her intelligent sons may see the importance of the new institution and encourage it in the only way that can lead to durable success—namely, by earnest study and hard laboratory practice.

The address begins by referring to the backward condition of Italy consequent on political misrule, and the paramount duty of every Italian to acquire political independence for his country. That desirable event having been accomplished, the next struggle was the endeavour to bring up their country to the level of more civilized nations. How was this to be done? Not by relying on the Government, but by their own exertions, in constructing railroads and other means of communication, developing the riches of the soil, encouraging industry; taking, in short, as their model, the Anglo-Saxon race—America and England.

The President goes on to show how false is the system of national prosperity that produces little and consumes much, exports nothing, imports everything; that produces few or no results of public education, while the population is uneasy and miserable. Trade and commerce are depressed, and those who should foster them are discouraged, because the system pursued is a false one. What is wanted for Italy is the development of her internal riches, and the knowledge how to apply science to her everyday wants.

"Banished from my native country by the political events of 1848-9, I have laboured and studied in different parts of Europe, in Asia, and the two Americas, to understand the secret of national prosperity. I returned to Italy, and excited my countrymen to follow the example of the stranger. I was laughed at! By good fortune I have had the privilege of founding this centre of instruction and research, although opposed by the Government and the municipality. The chief object of this Faculty of Chemistry is to instruct Italians in analytical chemistry and its application to industry, and then to distribute the men so educated over the country. Another object is to bring the scientific Italian out of his retirement and make his pulse beat in unison with that of his fellow-citizens—to win him, in fact, to the side of national industry, and make him more esteemed in his native land."

Italy is beginning to feel the importance of the call. Various municipal and other bodies have sent minerals to be examined, and the Faculty is already in a condition to declare that Italy has undeveloped wealth in every kind of industry. Search has been made for coal, that great motive force, and in spite of the opposition of Government and of the municipality of Naples (expressions that occur more than once, and which we confess we do not understand), the province of Naples can supply that great need.

He then goes on to show how to make the exports and imports more nearly balance each other. The imports in Naples and the surrounding districts amounted to 200,000,000 lire per annum,[*] and the exports to only 36,000,000. He proposes to work the metallic ores of the country by means of companies, to extend railroads, &c.

The School of Chemistry, the only one in Italy (!), was founded in 1866, and has already acquired much precise knowledge as to the natural wealth of the country. It is strongly recommended that the youth of Italy be educated in the theory and practice of the sciences; in facts and observations, and not in dry themes. The Faculty has already supplied two Lyceums with the chemical apparatus required for instruction, and the University has also sought its aid. It has sent several chemists to different parts of Italy, and it carries on a wide correspondence with persons who require information on scientific subjects.

The analyses performed by the Faculty had been liberally paid for with one exception, and that was on the part of the Government. One of the departments sent a liquid to the Faculty to know if it were adulterated, and on returning the analysis the fee demanded was refused, on the ground that the Faculty was a public department, although all its documents bear the words "*iniziativa privata.*" It is stated as one of the worst features of modern Italy that it grudges the scientific man his fee, while the number of useless officials that devour the public wealth is legion.

An exhibition of national products would be useless until there is a larger number of producers. It is to be deplored that many Italians are gratified with an honourable mention and a poor medal, while the maccaronis, once especially a native product, are now made of Russian flour, and are eaten with a French fork off an English plate.

It appears that the King had offered the President a house and 400 lire per annum if he would establish the Faculty at Turin, while both house and endowment were refused in Naples. "Such," he says, "is the Government patronage of science in Italy, at a time when the Prussian Government was expending 500,000 lire on the building alone of a laboratory of instruction in Berlin." He calls upon the people to get out of the leading-strings of the Government, and to think and act for themselves, although, somewhat contradictory to this advice, he suggests that a law be passed requiring every commune to set aside an annual sum for the purposes of scientific inquiry.

There are other suggestions, sensible enough in their way, but remarkable to us only for being so obvious. On the whole, we are gratified with the manly spirit of the address, in spite of a little too much self-assertion and recrimination, and think it creditable to the Government that young Italy can enjoy such freedom of speech. The very elementary nature of the address, and of the proposed remedies, show how degraded poor Italy had become under long years of political misrule. That there should be only one establishment in Italy capable of conducting a chemical analysis, and that establishment a private one, from which a University is taking lessons, is indeed a commentary on the oft-repeated proposition that when a nation loses its political freedom it must part also, sooner or later, with its science, its literature, and its art. It cannot become enslaved in body without being also enslaved in mind.

Chemical Notes for the Lecture Room. By Dr. Wood, F.C.S. London: W & H. Warr & Co., Featherstone Buildings, Holborn. 1867.

---

[*] The lire is worth 9½d.

For the matriculation examination of the University of London, an examination that has acquired of late years very considerable importance, a knowledge of chemistry is insisted upon quite as fully as a similar knowledge of any other branch of education. If a candidate be rejected for not gaining the minimum number of marks in any one subject, he has to pass in all the others again at a future examination. Last year 641 candidates presented themselves, and of these 334 were rejected; in 1865, 397 out of 616. An ignorance of chemistry is a very fertile cause of these rejections, and candidates generally complain of this subject as being one of "the stiffest." Very few fail, it seems, in mechanical philosophy. This is accounted for by the existence of a book, recognised as being the one necessary to work up thoroughly, and almost universally employed in the latter subject; while in chemistry the beginner, in an absolute sense, confuses himself by a mass of details, without the corresponding impression from seeing lecture experiments. Dr. Wood has endeavoured to prepare a short text-book on the subjects required, to answer the same purpose that Newth's "Mechanical Philosophy" now serves in another subject. We think that he has succeeded in a difficult task, but those who read the book will require to know it well. We need not talk of Dr. Wood's knowledge as a chemist, but we may mention that as a teacher he is widely known, and few chemists have more knowledge of what is required by candidates for the before-mentioned examination, and for whom the book is almost specially framed.

It is a capital guide-book for lecture experiments, although, as the author remarks, it is in no wise intended "to supersede the excellent works of Miller, Roscoe, and others"—we presume that he means for this particular examination. It will form, as he remarks, a book of easy reference. As an additional recommendation, the wording of expressions and symbols are "the very latest out."

Guide to Croft Spa. Third Edition. Darlington: J. & J. Burney, *Telegraph* Office, High Row. 1866.

In the Chemical News, September 14, 1861, a detailed account was given of the chemical properties of the waters of this spa. It will be seen from that notice that three of the springs there contain more sulphuretted hydrogen than any other mineral springs in England. We are glad that the prosperity of Croft Village has called for a third edition of this very complete guide to its spa.

On the Poisons of the Spreading Diseases. By B. W. Richardson, M.A., M.D., F.R.S. London: John Churchill & Sons, New Burlington Street. 1867.

This reprint of the famous lecture delivered at the Leamington Congress last year, will give some satisfaction, and almost as much disappointment. The satisfaction will be derivable from the many forcible truths and collection of facts; the disappointment caused by their admixture with so much that is mere statement, sometimes almost dogmatic.

Every reader of the book will find this to be a difficulty, for it will be necessary for him to winnow, we will not say the grain from the chaff, but the more healthy corn from the other grains mixed with it.

Although opposed from principle to the practice of ladies attending sanitary congresses and interesting themselves in the details of sewage, we find from the present case that fewer evils than we supposed were without an attending good; for the reflection that the Congress would be of a miscellaneous character, "at which perhaps ladies might be present as well as gentlemen," has been the cause of the selection of the subject of this paper—a paper we honestly think of very great value in much of its substance.

The form that we should like to see this valuable matter assume, would be that of detailed experiments given, and after this the author's deductions from them. The one would remain as valuable staple matter of reference; as regards the latter, a verdict might be given by every reader. There is no doubt that Dr. Richardson has found entirely satisfactory evidence of everything that he asserts; but every thoughtful reader must decline to record a similar conviction for himself in the absence of the evidence.

We have fifteen diseases given arbitrarily as those produced by *organic* poisons, organic being used in a sense of its own. Thus strychnine would not be an organic poison; it is not asserted, however, that it is an inorganic one. In this list small-pox appears as produced by organic poison, boil and carbuncle with infections ophthalmia (*Ophthal. Egyptorum?*), but chicken-pox, cow-pox, dysentery are excluded. Typhus appears in the list, and very strong evidence has been tendered of the connexion of dysentery with typhus, and cases, with no apparent fallacy, have been recorded of epidemic dysentery brought from India on board ship causing a typhus outbreak in port by direct infection. Such facts ought not to be ignored in a critical examination of which every step is attended with difficulty. And thus on almost every page the eye is arrested by some very knotty question comfortably disposed of. This renders a detailed criticism a work of almost indefinite length.

To choose a few sentences at random. "Each poison has a specific property always bringing out the same disease through countless ages. All are destroyed by oxidising agents. . . . Exposure to nitrous acid has the same kind of effect; exposure to sulphurous acid likewise produces destruction." "Common sulphur preserves them very well; the poisons of hospital fever I have been able to preserve for months by this means." (Query: What means?) "The poisons will all dry solid. There is no exception to this rule." (Query: Who has examined this?) "Sulphur, creasote, and arsenic hold these organic poisons in perfect steadiness; they preserve their active properties."

All these quotations require support from experiments, original or otherwise, for any judgment to be formed. Again, "There is reason to believe that in the decomposition of sewage water cholera poison may be developed." These quotations are all from two or three consecutive pages, and are accompanied by many others of the kind.

Is our demand for a detail of experiments then unjustifiable? If these are not forthcoming, England must yield the palm to America; for Dr. Richardson quotes some experiments that are convincing.

"During the great American struggle, Dr. Salisbury observed that a large number of men rose one morning with symptoms of measles. . . . The men attributed their illness to the straw upon which they lay. . . . Dr. Salisbury removed from the straw certain portions of fungus; he had the courage to inoculate himself with the fungus, and he thus produced measles. He then inoculated *his own wife*, and then *a mother and four children*, then a mother and two children, and produced in all the same disease." We must leave the reader to judge of the feelings of the ladies present at this great sanitary congress.

Chemical Technology; or, Chemistry in its Application to the Arts and Manufactures. By Thos. Richardson, M.A., Ph.D., F.R.S.; and H. Watts, B.A., F.R.S. Second Edition. Vol. I. Part V. London: H. Baillière, 219 Regent Street. 1867.

This second edition of a well-known volume has given an opportunity for several important additions, with an announcement of the parts necessary for the completion of the series.

The work itself has already acquired imposing size, and the complete set forms in itself a library for the manufacturing chemist, who, indeed, could do without it altogether with difficulty, and would incompletely replace it as his book of reference by a great mass of materials—such a mass, in fact, as must of necessity be consulted by competent chemists for the successful completion of a scheme like this.

The first volume is formed of five parts, each of octavo size, with from 800 to 900 pages. Parts I. and II. contain Fuel and its Applications; Part III., Acids, Alkalies, and Salts; Part IV., Aluminium, Sodium, Phosphorus, Lucifer

Matches, Borax, Artificial Mineral Waters, Gunpowder, Guncotton, Fireworks, &c; and the present volume, Part V., Prussiate of Potash, Oxalic Acid, Tartaric Acid, Tartrates of Potash, and Citric Acid, with appendices presently to be noticed. We have thus four handsome books forming Volume I. Volume II. contains Glass, Alum, Potteries, Cements, Gypsum, &c., &c. Volume III., Food generally, Bread, Cheese, Tea, Coffee, Tobacco, Milk, Sugar.

These three volumes are all that have at present appeared; they form six octavo books of large size, illustrated with woodcuts, plates, engravings, and, in the last volume, coloured plates.

The book itself is rich in passages we should like to quote, were it not for their length. There is, however, one value connected with a work of this kind which ought to be pointed out. Most young chemists, after passing through the routine course of their scientific education, feel somewhat at a loss to know in what direction to turn their experimental energies, so as to obtain a prospect of some return for their trouble. As we stated in these pages a few weeks ago, it often happens that a difficulty is found in carrying out some manufacture which could easily be overcome, by a short investigation, by a competent chemist; and, indeed, in many cases a difficulty which appears insuperable to the manufacturer, would prove a mere *bagatelle* to the chemist. The difficulty, however, is for the young experimentalist to know what are the problems in industrial chemistry which require solving. In this respect the present series of Chemistry Applied to the Arts and Manufactures constitutes a very mine of wealth. As an illustration, we learn that with regard to the determination of the commercial value of tartars, it is a point of the utmost importance that some method should be devised for ascertaining correctly the quantity of tartaric acid present, which is now merely deduced from the quantity of potash found.

That this method is by no means an accurate one may be seen from the three following analyses of the same sample, viz:—

Tartaric acid present as bitartrate of potash,	70·15	69·10	72·25
Tartaric acid present as tartrate of lime,	3·35	3·30	3·75
Total crystallised tartaric acid, per cent.,	73·50	72·40	76·00

This is so urgent a matter, that one of the largest and most distinguished manufacturers of tartaric acid has expressed his willingness to give 100*l*. as a reward to any one who would discover a satisfactory method of determining, directly, the quantity of crystallisable tartaric acid present in tartars, in a sufficiently ready manner to be applicable to commercial analysis. This is only one of the many chemical problems to be met with throughout the work, the solution of which would be attended with considerable profit.

The following are announced as in preparation to complete the work:—Vol. IV. devoted to Liquid Food, Ales, Wines, Spirits, &c.; V. and VI. to Textile Manufactures, Cotton, Wool, Silk, &c.; VII. to the Manufacture of Leather, Gutta Percha, &c.; VIII. to Manufacture of Paper, &c.; IX., X., XI., to Metallurgy and Chemistry of the Metals; XII. to the Manufacture of Colours, Oils, and Varnishes. These will complete an elaborate and exhaustive work, which English chemists will mention with pride, as a proof of the repute in which chemistry is beginning to be held in our country. It seems that no space will be given separately to the consideration of the preparation of medicinal substances in a pure form, such as morphia, chloroform, &c.

As regards this present edition of the volume under notice, no one will doubt the wisdom of the retention of the older notation of the former one, which is still most applicable to the wants of the manufacturer, who cannot be expected to be well acquainted with newer views held in 1867. The next edition will be in time for those of a younger generation now pupils at various laboratories.

Of the 900 pages of this part, upwards of 700 are devoted to the various appendices. Appendix A consists of additions to the various chapters of Vol. I., parts iii., iv., and v., first edition, and brings the report up to the present time; nearly 300 pages are devoted to this part of the work. Appendix B contains abstracts of specifications of patent inventions relating to materials and processes described in those parts; Appendix C (of the greatest value), tables connected with processes described in the former parts; Appendix D, documents relating to the Patent Laws, appearing at a very opportune time. A casual glance will show a great part of the value of all these appendices, but Appendix C is so important, and would be so useful for constant reference, that we would urge a publication of it separately; it would form a volume more easy for constant reference than in its present form. Lastly, we think that the whole of the additions to the first edition, which form the bulk of the book, ought with justice to be prepared also in a separate form. Possessors of the first edition should not be expected to buy the whole volume, part of which they already possess. The same reason should have weight with the publishers, when the time comes for newer editions from time to time. If this were promised, the different parts would have a lasting value even to a greater extent than at present; besides this, the latest information could be more frequently supplied, to supply a more extensive demand. The plates, five in number, are excellent; two of them consist of tables and scales, the other three of apparatus, &c. It would have been better if the paper for these had been of a stronger kind, or mounted on some material to make them more durable for frequent reference. We commend a consideration of this point to Messrs. Richardson and Watts for discussion in the forthcoming volumes relating to textile manufactures and the manufacture of paper.

"Chemical Technology," clearly and accurately written, neatly sent to press, and very moderate in price, may justly be a source of pride to the authors, the publisher, and the profession generally.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Bulletin de la Société d'Encouragement. January, 1867.

NOTICES OF PATENTS.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

218. E. H. C. Monckton, Summer Hill, Birmingham, "Improvements in the manufacture of butter."—Petition recorded January 26, 1867.

952. W. E. Newton, Chancery Lane, "An improved process for manufacturing ice and for other refrigerating purposes." A communication from T. S. C. Lowe, New York, U.S.A.—March 30, 1867.

979. J. Storey, and W. E. Bickerdike, Lancaster, and W. V. Wilson, Jubilee Street, Mile End, Middlesex, "A new method of bronzing metallic and other surfaces."—April 2, 1867.

1044. W. R. Lake, Southampton Buildings, Chancery Lane, "An improved mode of embalming or preserving dead bodies and carcases." A communication from G. W. Scollay, St. Louis, Missouri, U.S.A.—April 6, 1867.

1054. C. F. Claus, Middlesbrough-on-Tees, Yorkshire, "Improvements in the manufacture of chlorine."—April 8, 1867.

1064. J. H. Player, Birmingham, "Improvements in the manufacture of phosphorus and in economising residual products of the said manufacture."—April 10, 1867.

659. W. R. Lake, Southampton Buildings, Chancery Lane, "An improved mode of coating paper and other materials with fluid substances, solutions and compounds for photographic and other purposes." A communication from J. C. Crossman, Boston, Mass., U.S.A.—Petition recorded March 8, 1867.

1042. W. Henderson, Glasgow, "Improvements in oxidising minerals, ores, and metals; in reducing oxides of metals; in separating certain metals from each other; in kilns, furnaces, or other apparatus for these purposes; and in the treatment of the products obtained therefrom."—April 6, 1867.

1087. W. H. Dawes, West Bromwich, Stafford, "An improvement or improvements in the manufacture of iron."

1091. C. Wilmet, Brussels, "An accelerated tanning by means of new processes and apparatus."—April 12, 1867.

1099. J. Aitken, Tottington Higher End, Lancashire, "Certain improvements in apparatus employed in the process of refining sugar."

1107. C. Crockford, Holywell, Flintshire, "Improvement in obtaining useful products from certain materials produced in the process of galvanising or coating iron with zinc."—Petition recorded April 13, 1867.

1118. The Rev. J. Oakden, St. Stephen's Parsonage, Congleton, and J. Picking, Dane Row, Buglawton, Congleton, "A new or improved enamel for enamelling metals and stones, to prevent rust, corrosion, and incrustation." April 15, 1867.

1190. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in the treatment of peat, and in the manufacture of peat charcoal, and in the machinery or apparatus employed.

therein." A communication from A. Figge, Hanover.—April 24, 1867.

1198. C. E. Brooman, Fleet Street, "A new or improved process of destroying vegetable matters in wools, noils, woollen waste, and rags." A communication from C. Schaller, Bischweiler, France.

1200. C. E. Brooman, Fleet Street, "A new or improved process of preserving meat, fish, and other substances." A communication from F. Cirio, Turin, Italy.—April 25, 1867.

NOTICES TO PROCEED.

3293. F. W. Reeves, Cambridge Terrace, Notting Hill, Middlesex, and J. B. Muschamp, Pembroke Road, Middlesex, "An improved explosive substance."—Petition recorded December 15, 1866.

3226. L. Schad, Warrington, Lancashire, "Improvements in treating aniline colours for dyeing and printing."—December 18, 1866.

3348. S. Parry, Thackeray Street, Liverpool, "An improved composition for the coating of the bottoms of ships and other vessels."—December 20, 1866.

3433. J. Napier, Salisbury, Wiltshire, "Improvements in the preparation of food of a substance to be employed in the place of malt, and for the medication of food for animals."—December 29, 1866.

211. J. J. Lundy, Leith, Mid Lothian, N. B., "Improvements in the treatment of the residual matters resulting from and obtained in the purification and distillation of mineral or hydrocarbon oils, and also in the treatment of coal-tar and various waste or other alkaline and lime substances, for the purpose of utilising the same."—January 26, 1867.

3307. C. E. Brooman, Fleet Street, "Improvements in the preparation and application of certain fatty bodies." A communication from M. P. Javal and E. P. Javal, Paris.—Petition recorded December 15, 1866.

22. W. Knaggs, Euston Grove, Euston Square, Middlesex, "Improvements in apparatus for evaporating and boiling saccharine liquors."—January 3, 1867.

47. W. Way, M.D., Eliot Place, Blackheath, Kent, "Improvements in preparing phosphatic minerals for use as manure." Partly a communication from C. Henwood, Sombrero, West Indies.—January 7, 1867.

250. E. V. L. Ebersburg, Knightsbridge, Middlesex, "A new or improved article of food for infants and invalids." Partly a communication from Baron J. von Liebig, Munich, Bavaria, Germany.—January 30, 1867.

819. J. Greenshields, Glasgow, N.B., "An improved compound or combination of materials to be used for the production of illuminating gas."—March 21, 1867.

935. J. Bird, Seymour Street West, Connaught Square, Middlesex, and J. Bird, Laurence Pountney Hill, London, "Improvements in the manufacture of artificial fuel."—Petition recorded March 29, 1867.

952. W. E. Newton, Chancery Lane, "An improved process for manufacturing ice, and for other refrigerating purposes." A communication from T. S. C. Lowe, New York, U.S.A.—March 30, 1867.

1042. W. Henderson, Glasgow, "Improvements in oxidising minerals, ores, and metals; in reducing oxides of metals; in separating certain metals from each other; in kilns, furnaces, or other apparatus for these purposes; and in the treatment of the products obtained therefrom."—April 6, 1867.

1153. W. Harrison, Wharton Green, Winsford, Cheshire, "An improved method of consuming smoke in furnaces."—April 20, 1867.

2077. *Making Caustic Soda from Common Salt, by the Action of Lead or its Oxide, with After Recovery of the Lead for further Use.* S. ROWBOTHAM, Penkett, near Warrington. August 14, 1866.

THE sodic chloride is either fused with the lead or mixed with plumbic oxide and water until decomposition takes place. Heat may or may not be necessary; the whole is kept moist by steam. The caustic soda is separated by lixiviation. The plumbic chloride left is then exposed to the action of oxygen with heat, or steamed to recover the lead or its oxide. The lead is further to be purified by the action of charcoal.—Patent abandoned.

2095. *Coating and Recovering Metals from Chlorides and other Solutions of Metals.* J. WEBSTER, Birmingham. August 15, 1866.

CHIEFLY applied for using the zinc chloride in the flux used in the pots for galvanising iron. This is boiled in a cast-iron vat; when the temperature reaches 600° Fahr., scraps of tin or wrought iron from other manufactures are added. The vat has a longitudinal partition, which is a grating or perforated plate to allow of free diffusion: in one half the scrap tin or iron is placed, in the other articles that require a coating of zinc or tin. In this also scrap materials must be placed and pressed on the bottom of the vat by another perforated iron plate for the hydrogen gas to escape. Copper, brass, &c., by such a coating of zinc or tin, are protected from atmospheric action.

CORRESPONDENCE.

Cement Cisterns for Water.

To the Editor of the CHEMICAL NEWS.

SIR,—I find among the answers for correspondents in No. 386 of your valuable paper, an excellent suggestion to J. Y. S. Permit me to call your attention to the use of hot coal tar for preventing the contamination of the water by the cement. It is a cheap and effective means of preventing what is complained of, and is not a fancy. Experiments made by Captain de Bordes, of the Netherlands Royal Engineers, and myself, many years ago, have proved that even from hydraulic cement which sets and hardens in a few hours, for days after lime and other salts are dissolved out by pure distilled water in very appreciable quantity. In the kingdom of the Netherlands, in many parts, and especially in portions of the provinces of Zealand, North Holland, and Friesland, no other water than rain-water is in general use for domestic purposes, because, like as at Amsterdam, Flushing, the Helder, and other places, all the water of canals, rivers, &c., is either brackish or decidedly salt. Large cisterns built under ground, in order to prevent foul infiltrations of surface-water, but which have to be laid entirely in strong cement (hydraulic as it is termed), are used to keep the rain-water for the use of barracks and large establishments. These cisterns are often lined with Dutch glazed tiles, fixed in cement, but it has been found cheaper to simply line the cisterns with cement, and after it is dry to give two coatings of hot coal tar. I suggested lately the same to an engineer, who, having applied it to a cistern of his own in his house, found it to answer perfectly. For a few days the water had a slight tarry taste, which is now entirely gone. I am, &c. DR. ADRIANI.

Drilling Glass.

To the Editor of the CHEMICAL NEWS.

SIR,—In the CHEMICAL NEWS of April 19 there is a description, by Mr. Spencer, of the old and well-known method for drilling glass by means of a file wetted with oil of turpentine. Some years ago I read in a German periodical of another means for the same purpose—viz., dilute sulphuric acid—and I found it, on trial, to answer much better than the first. Not only, it appears, is the efficacy of the cutting tool more increased by sulphuric acid than by oil of turpentine, but also, strange as it seems, the tools (files, drills, &c.) are far less rapidly destroyed by being used with the acid than with the oil. I also found it stated that, in the engineering establishment of Mr. Pintus, at Berlin, glass castings for pump barrels, &c., were drilled, planed, and bored, just like iron ones, and in the same lathes and machines, by the aid of sulphuric acid. As to drilling, I can fully testify to the efficacy of that method.

Whenever I want, say, a hole in the side of a bottle, I send it, along with some dilute (1 : 5) sulphuric acid, to the blacksmith, who drills in it, with a hand-brace, a hole of ¼-inch diameter. This hole is then widened to the required size by means of a triangular or round file, again wetted with the acid. I also find a great help in the latter when making graduations on litre flasks, &c. There is hardly any smell perceptible during the work, which proves how little the acid acts upon the tools, undoubtedly owing to their being tempered; but each time after use I take the precaution to wash and dry the files at once, and I have so far observed no sensible deterioration in them. Hoping this little hint may be useful to some of your readers, as it has been to me,

I am, &c. G. Lunge, Ph.D.

South Shields, April 22.

Department of Science and Art.

To the Editor of the Chemical News.

Sir,—As you have occasionally admitted into your columns strictures upon the operations of the Department of Science and Art, attacking now its supposed procrastination, now its inconsistency, and now its impolicy, allow me to submit to you the accompanying extract from a printed notice, which will show, at least, the generous intentions and liberality of the Council on Education towards its certificated science teachers, and which will, I hope, prove their sincere wish to foster the spread of an intelligent scientific taste among the people. It will also furnish some reply to those who have lately questioned the justice or desirability of retaining a special class of beneficed teachers; for it is obvious that were there no limitation to the number of claimants, such a bounty as that which the Government here offer—viz., of paying the expenses of each certificated master who shall visit the Paris Exhibition—would become impracticable. I believe a score of other good reasons could be given why teachers should conform to rule and submit themselves to examination before benefiting from the national grant; and so far from advocating the abolition of such tests, I, in common with many others, would rejoice to see the already high standard of qualification raised, as it is quite possible that the Department may design—it is time to grumble after we have seen their next May's questions—but I feel that it is absurd to expect the Department to continue to apply their vast machinery to the examination of sometimes a solitary candidate, as was my own case on a certain day last November. I am not surprised that they should meditate making the season of examination of both masters and pupils identical. That the questions proposed to each will be identical is now at least problematical; but were they the same it cannot be supposed but that such an experienced professor as Dr. Hofmann (even with his 1500 candidates) could perfectly discriminate by a series of judicious questions between the proficiency fitting for a teacher and that to be expected from a student; while the grouping together of both classes of men in the same grades, though it may mortify the vanity of incompetent or idle would-be lecturers, is at the same time an additional spur to such as have the pride to excel, from the fear lest distinguished pupils of other schools should be classified as their equals. I beg to subscribe myself as one who, though previously qualified to claim receipt of grants on result, yet preferred to submit to routine and become, after examination, A Certificated Master.

April 26.

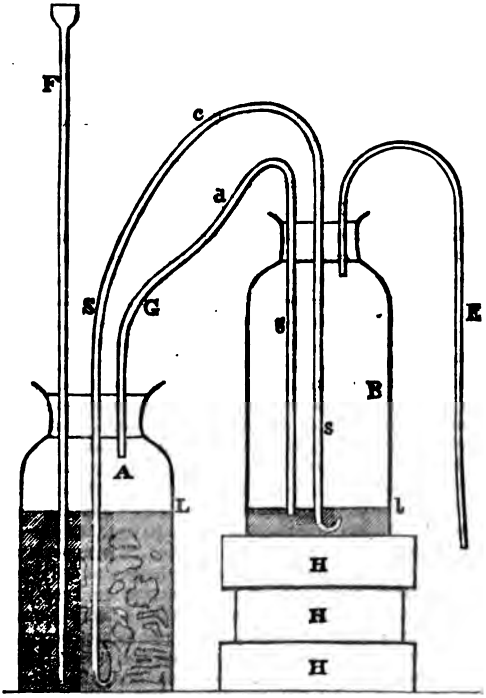
"Their Lordships announce to the certificated masters now engaged in giving instruction in schools of science and art connected with the Department, that they will pay to each such master or mistress visiting the Paris Exhibition, the sum of five pounds in aid of their expenses, and to each an additional sum of two pounds for any report or any useful suggestions which any such teacher may make (in respect to his or her duties or teaching) derived from the study of the Exhibition, such report having first been published in any journal local or otherwise, and afterwards approved by their Lordships. And further, to each of the three best of such reports referring to instruction in science and to each of the three best reports referring to art, my Lords will give respectively the following prizes in addition to the sum above named, namely,—for science, for the best report, twenty pounds; for the second best report, fifteen pounds; and for the third best report, ten pounds, and the same sums respectively to the three best reports for art."

Improved Sulphuretted Hydrogen Apparatus.

To the Editor of the Chemical News.

Sir,—I venture to describe a modification of apparatus for generating sulphuretted hydrogen, which will, I trust, recommend itself to the laboratory on the grounds of compactness and cheapness, combined with effectiveness.

It consists essentially of a generator and a wash-bottle united (in addition to the ordinary connexion) by a siphon, whose legs dip to the bottom of each vessel; it occupies, therefore, the same space as the simplest arrangement, while the production of gas may be rapidly arrested or controlled at pleasure without the escape of noxious effluvia. Its cost of construction need not exceed one shilling, while it affords even greater conveniences than the more costly adaptation described at p. 152 of the *Journal of the Chemical Society*, 1864.



My apparatus consists of two similar wide-mouthed bottles, A and B, whose bungs (or, preferably, whose caoutchouc capsules) are pierced each by three holes. A is the generator, supposed in action; B is the washbottle, which serves also, during inaction, as a reservoir for the exciting acid; F, a tall thistle-headed funnel passing to the bottom of A, by which it is charged, and which serves also as a safety-vent; S, *s*, the siphon limbs, which dip to the bottom of each vessel, and are slightly recurved at the orifices; *c*, *d*, caoutchouc connectors; G, *g*, the transit pipes for the gas as generated, the former terminating at the top, the latter at the bottom of their respective vessels; E, the eduction pipe; H, blocks used to relatively raise or depress each bottle as occasion requires.

Previous to operation, A is filled a quarter full of broken glass; on this are laid lumps of ferric sulphide, which are thus prevented from choking the ends of F and S; acid is poured in through F till A is three-quarters full; the siphon is then charged by nipping the other bend *d*, when the pressure of gas formed in A should be suffered to force the contained liquid over the bend *e* into B, till the mouths of *g* and *s* are covered, and the acid stands at the same level in both bottles, as in the figure L, *l*. B is then raised on the blocks H, and *d* is unnipped, when the gas will commence flowing in its normal direction through G *d g*, and, bubbling through the wash-bottle B, will pass out at the eduction tube E. When it is desired to stop the action, A is raised on the blocks, and B depressed; the former will then be emptied by the siphon into the latter; the reverse will take place, if, with a view of re-exciting the sulphide, the levels be again interchanged.

Your readers' ingenuity will suggest how, by varying the elevations, the flow of gas may be regulated to a nicety, or the charge of acid renewed without opening the bottles or emitting any smell. The eduction tube should, after traversing the solution to be impregnated with H_2S, always finally dip into a bottle of strong liquor ammoniæ, which will absorb any excess of unused gas, thus furnishing a useful laboratory reagent as a by-product.

Should the siphon become inoperative from gas collecting in its bend, which may occur through inadvertently over-emptying either bottle, or from effervescence passing up its limb S, it may be readily recharged as at starting.

Such an arrangement is of course equally applicable to other gases of daily use in the laboratory, for each of which such an inexpensive apparatus might be reserved.

I am, &c., B. W. Gibsone, M.A., B.Sc.

Eaton Square, S.W., April 8.

Extinction of Fires.

To the Editor of the Chemical News.

Sir,—In papers dated Sydney, February 16, I find an account of a patent taken out by Dr. Bland for a method of extinguishing fires in ships' holds and other confined spaces by means of carbonic acid gas. The patentee states that his attention was directed to the subject by the loss of a ship by fire in 1839, and now, after twenty-eight years of, no doubt, laborious experiments, he brings forth the following original process. He places on the keelson of a vessel a number of barrels containing calcareous minerals, and generates carbonic acid gas by the action of dilute acids supplied by tubes from the deck above. The gas finds its exit by numerous holes bored in the upper part of the barrel. The inventor of this brilliant process invited to his establishment at Woolloomooloo, Sydney, a number of gentlemen, members of the legislature, &c., to witness the success of his patent, but the result was in keeping with the former details. His apparatus for confining the combustion to a closed space was so clumsily constructed that sufficient air found access to keep up the combustion in spite of the supply of choke-damp generated from whiting spread on "iron plates," not from a barrel.

It is sincerely to be hoped that we are not to be prohibited by letters patent from employing carbonic acid gas, generated in any off-hand apparatus, to extinguish combustion. This patent seems about as novel as the caustic soda process of Mr. J. Roddy, mentioned in the last volume of the Chemical News.

I am, &c. T. B.

Manchester, April 26.

The Chemical Society.

To the Editor of the Chemical News.

Sir,—Your leading article in the Chemical News of Saturday-last interested me. I have long been expecting to see evil effects arise from the admission of so many persons into the Chemical Society who are manifestly unworthy of that honour. I mean persons who simply pay the fees, and do not promote chemistry either by original communications, or in any other way worthy of the title F.C.S. The following circumstance may perhaps interest you, as it relates to this subject:—A junior partner in a manufacturing firm was admitted into the Chemical Society; on being asked what chemical investigations he had made to entitle him to that honour, he replied that other persons made investigations, besides those who published them, meaning thereby that he had made chemical investigations, but did not publish them. The objects of the Chemical Society are defined to be "the promotion of chemistry, and of those branches of science immediately connected with it, by the reading, discussion, and subsequent publication of original communications." The admission, therefore, into the Society of persons whose practice (as in the above instance) is to monopolise chemical knowledge, and keep it secret for their own personal advantage only, is contrary to the objects for which the Society exists; it is also conferring an honour upon persons who do not adequately deserve it. Further, the admission of persons whose only object is to promote their trades, and the getting of money by them (however worthy those objects are in themselves), is unjust towards those members who, at considerable sacrifice and much self-denial, aid in the extension of chemical knowledge.

I am, &c.,

F.R.S., F.C.S.

Caramel Colours.

To the Editor of the Chemical News.

Sir,—Under the "Notes and Queries" in your valuable paper (No. 387), I happen to find one concerning caramel. Perhaps the following may be of use to your correspondent.

The manufacture of caramel (coffee finings, as it is often termed in London) is kept a secret on this account, that neither coffee-roasters, nor dealers in groceries, nor brewers, may have, or at least are presumed not to have, any in their possession—the Excise prohibiting it. Here in London it is made by roasting sugar of coarse description in cylinders similar to those used for roasting coffee, chicory, and cocoa; this yields a very inferior preparation both for colouring as well as for admixture with coffee. So prepared it contains assamar and other pyrogenetic products which are very bitter. On the Continent apples of inferior description are treated as described, yielding a product superior to that obtained from sugar. Sugar, however, is the only fit material to prepare caramel, and for this purpose the sugar is best heated in capacious roomy vessels made of copper (in Vienna copper lined with silver is preferred), the vessel containing the sugar being placed in an oil bath* containing a thermometer to indicate the temperature. The latter must not be below 410° nor above 428° Fahr. The heating of the sugar is continued as long as aqueous vapours are given off. The crude caramel so obtained is best purified by being placed upon a parchment paper dialyser, which is placed on water. The undecomposed sugar and intermediate compounds are thus got rid of; they dissolve out with facility, and what remains on the filter is, weight for weight, five times as strong in colouring matter as the crude caramel. While the sugar is being exposed to heat it is preferable to stir it with a spatula.

Another mode of obtaining a pure caramel, free from bitter produce (assamar and the like), is to heat the sugar as above, and to treat the powdered caramel with alcohol (pure methylated spirits), to digest it for three to four hours therewith, and repeat this till all bitter taste is gone. An aqueous solution containing 10 per cent. of purified caramel is gummy, and forms a jelly. When a solution of caramel in water is evaporated *in vacuo* (small vacuum pan as used in sugar refineries), it dries up to a black shining mass, freely soluble again in water, hot or cold; but if the solution is evaporated on a waterbath to dryness in contact with air, the whole mass becomes insoluble in water either hot or cold.

---

* A mixture of tin and lead is sometimes used, just made so as to remain fluid at from 412° to 430° Fahr.; some bismuth is added.

A very small proportion of caramel gives to a large bulk of water the dark brown tinge known as sepia. An impure but pretty strong solution of crude caramel (*i. e.*, not purified by dialysis or alcohol—hence the term impure for the solution) is sold in London under the name of coffeena in small bottles at 1s. per bottle, to be had in many oil and colour shops in the metropolis; it is used in teaspoonfuls to improve coffee, dispensing with chicory.

I am, &c., A. Adriani.

London, May 7.

P. S.—Treacle is not very manageable to use for the making of caramel. The sugars should be first dried at 212° Fahr. On the Continent dry glucose is sometimes used instead of cane or beetroot sugar for the purpose of making caramel.

Transparency of Red-hot Metals.

To the Editor of the Chemical News.

Sir,—One of the contemporaries, though not a strictly scientific periodical, of your valuable paper, calls attention to a highly curious and startling fact observed and communicated by the reverend and highly eminent *savant*, Father Secchi, of Rome, concerning the transparency of iron while red-hot. The fact that iron, steel, and also platinum and copper, are transparent while at a bright red heat, has been known long since, not only to practical engineers, but, as regards iron, steel, copper and platinum, to workers in these metals. The account given of the manner in which the excellent member of an eminent society found out this property of iron is as follows: The reverend Father had ordered a strong iron tube to be made. As it was intended for an apparatus requiring a vacuum, it was essential that this tube should be perfectly air-tight; and as Father Secchi had some doubts about its soundness in this respect, in order to set these at rest the tube was made red-hot and taken into a dark place, when Father Secchi clearly perceived through the iron, which was half a centimetre thick, a crack inside the tube, and which did not reach to the outer surface. It is rather curious that the fact of the metals above alluded to, to which I have reason to believe that gold may be added, becoming transparent at red heat should have escaped the notice of scientific men. It requires, however, a good bright red heat; but the transparency of the metals is evident thus even in daylight, as I know from my own experience while working in an engineering establishment attached to a large sugar refinery, now many years ago.

I am, &c., A. Adriani.

[The above statements are so much at variance with all previous ideas on the subject, that much stronger evidence will be required before the transparency of red- or white-hot metals can be accepted as proved.—Ed. *C. N.*]

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Alcohols, Synthesis of ($C = 12$).—A. Liben. It appears probable that the action of zincic compounds of alcohol radicals on chlorinetted ether, would be limited to the chlorine atoms, and afford the means of passing from one step in the series of alcohol to another. It was necessary, in the first place, to establish the constitution of chlorinetted ethylic ether. It appears that this is best expressed by

$$\left.\begin{array}{r}C_2H_3Cl_2\\C_2H_5\end{array}\right\}O.$$

By this light the body described by Lieben and Bauer as resulting from the action of zincic ethide on chlorinetted ether has the constitution expressed by

$$\left.\begin{array}{r}C_2H_3ClC_2H_5\\C_2H_5\end{array}\right\}O,$$

and should be called ethylochlorether. This body, under the action of iodhydric acid, gives ethylic iodide, ethylated ethylic chloride, and ethylated ethylic iodide, which last-mentioned body has the composition and boiling-point of Wurtz's butylic iodide. With argentic acetate it gives ethylated ethylic acetate and butylene, or a remarkable similar isomer of butylene. Ethylated ethylic acetate, when boiled with concentrated potash solution, gives ethylated alcohol, which is most probably isomeric with normal butylic alcohol, and identical with butylenic hydrate. If it be so, then Kolbe's conjecture that the ——enic hydrates are secondary alcohols is established. Viewed from the same standpoint, another body which has also been described by Lieben and Bauer as a product of the action of zincic ethide on chlorinetted ether, wherein both chlorine atoms are replaced by ethyl, becomes diethylether.

$$\left.\begin{array}{r}C_2H_3.C_2H_5.C_2H_5\\C_2H_5\end{array}\right\}O.$$

Iodhydric acid produces, with it, ethylic iodide and diethylated ethylic iodide, and from this we may expect to obtain diethylated ethylic alcohol, a secondary or tertiary alcohol isomeric only with hexylic alcohol. It is easy to foresee the synthesis, on those principles, of an almost endless series of different alcohols.—(*Ann. Chem. Pharm.*. cxli. 236.)

Mellitic Acid ($C=12$).—A. Baeyer gives, by letter, some results of researches undertaken in communion with Scheibler. Mellitic acid is hexabasic; it is benzol in which H_6 are placed by $(CO_2H)_6$. Heated with lime, it splits into benzol and carbonic dioxide; sodium amalgam adds H_6 to it, with production of a hexabasic acid $C_6H_6(CO_2H)_6$, which is converted by sulphuric acid into a tetrabasic acid, $C_6H_2(CO_2H)_4$, to which body H_4 may be added, and carbonic dioxide again expelled by sulphuric acid, when benzoic acid is finally obtained. To complete the series beginning with $C_6(CO_2H)_6$, and ending with $C_6H_5(CO_2H)$, three members of which have been studied, and to extend the researches on the group beginning with $C_6H_6(CO_2H)_6$, more material is required than the authors can command; they therefore entreat possessors of the rare honeystone to come to their assistance.—(*Ann. Chem. Pharm.* cxli. 271.)

Dinitronaphthalene and Potassic Cyanide. ($C = 12$).—Mühlhäuser. The reactions of potassic cyanide with nitro-compounds having been chiefly studied in the acid representatives of this group of bodies, it seemed necessary to extend the research in other directions, and dinitronaphthalene was chosen as a substance easy to prepare and purify. Pfaundler and Oppenheim, in 1865, made some experiments on the subject, but did not succeed in obtaining decisive results. An alcoholic solution of dinitronaphthalene is mixed with aqueous potassic cyanide solution, reaction occurs in the cold but is advantageously assisted after a short time by gradually heating to boiling. A fine blue-green colour marks the end of the reaction. On standing, the solution deposits the potassic salt of naphtocyamic acid $C_{22}H_{10}KN_6O_{10}$, easily soluble in hot water and in alcohol with a splendid blue colour. Its tinctorial power is very great; it explodes if heated; the baric salt is insoluble in cold water and in ether, easily soluble in hot alcohol; the argentic salt is almost insoluble in hot alcohol or water, and is very explosive. The free acid is uncrystallisable, insoluble in water, dissolving with brownish-yellow colour in alcohol or in a mixture of alcohol and water; it is bibasic. The acid and its salts are scarcely less sensitive to alkalies and acids than cyanin or irisine, for if water be shaken with magnesia, filtered, and mixed with a solution of the acid, the yellowish colour of the latter is immediately changed to bright blue.—(*Ann. Chem. Pharm.* cxli. 214.)

Ethylic Sulphate, Action of Ethylic Iodide and Zinc on ($Ba = 137$, $C = 12$).—A. Claus. Perfectly dry ethylic sulphate was digested with excess of ethylic iodide and granulated zinc; the reaction was fully accomplished at the ordinary temperature. The product is a solid dark-green, resinoid, semi-fusible mass. Water and ether were very gradually added to the contents of the flask until the violent reaction ceased; the ethereal solution, having been separated from the aqueous one, was distilled until the temperature rose above 100°; the retort then contained an oily liquid, in bulk about two-thirds of the ethylic sulphate employed, which, when further heated, began to evolve sulphuric dioxide. When all liquid had passed over, a loss of a quarter had occurred. This experiment was not, therefore, repeated, but the oil was boiled with successive small portions of baric hydrated oxide and water; the solution was saturated with carbonic acid, filtered, and evaporated; finally, crystals of $Ba.C_4H_{10}S_2O_4$ baric ethylsulphite were obtained. No other product of the principal reaction is described, but the fact that the addition of water in the first instance caused a copious deposit of zincic hydrated oxide suggests the formation of an intermediate zincic compound analogous to those obtained by Frankland and Duppa under corresponding conditions.—(*Ann Chem. Pharm.* cxli. 228.)

Nicotine (C=12).—Dr. C. Huber. When treated with chromic acid, nicotine gives an acid $C_6H_5NO_2$, yielding easily crystallisable salts and azo-compounds. Distillation with lime produces C_5H_5N, an oily base soluble in water. The first reaction also produces another acid richer in carbon, and at least one base. Details will be given at a future time.—(*Ann. Chem. Pharm.* cxli. 271.)

Styrol, Isomeric States of.—M. Berthelot. Styrol from storax possesses a rotatory power on polarised light. That from cinnamates has none. The former is more easily attacked by reagents, and, when mixed with sulphuric acid, disengages more heat than the latter. Polymers of styrol produced by the action of heat or of potassium reproduce at 300° the original styrol, whilst those produced by the action of sulphuric acid distil in part undecomposed, behaving, indeed, as mixtures of distyrol, volatile at about 300°, and more highly condensed and less volatile polymers.—(*Bull. Soc. Chim. Paris*, 1867, 112.)

Coal-tar, Synthetical and Analytical Studies on.—M. Berthelot. The reactions of benzol and ethylene at elevated temperatures give rise to styrol, naphthalene, anthracene, chrysene, and some other constituents of coal-tar, the parent substances being themselves directly derivable from acetylene. Another group of constituents—the benzol series—might be expected to result from the action of formene on benzol; but reaction occurs only at a temperature incompatible with the existence of toluol, and anthracene is produced—a fact not without interest, since toluol is converted by heat into anthracene. Free formene differs therefore from free ethylene in its behaviour with benzol at high temperature. To obtain formene and benzol in presence of each other and nascent, a mixture of sodic acetate and benzoate was heated. A small quantity of toluol and a mixture of probably higher benzol homologues were obtained. The synthesis of toluol involves that of toluidine and of numerous other coloured coal-tar derivatives. The group of constituents which may be represented by aniline was studied in that member. A mixture of benzol and ammonia passed through a red-hot tube produced small, but unmistakable proportions of aniline. The oxygenated bodies—phenol, &c.—will be commented on at a future time. With respect to the analysis of coal-tar, cumol at a red heat gives rise to precisely the same series of hydrocarbons as contained in that complex mixture.—(*Bull. Soc. Chim. Paris* 1867, 113.)

Thermo-chemical Conditions of Pyrogenic Reactions.—M. Berthelot. Ethylene combines readily at a high temperature with hydrogen and benzol, acetylene heated with many hydrocarbons combines with them freely; formene, water, carbonic dioxide, heated with hydrocarbons, either do not combine with them, or do so at a very high temperature only. The reason of this difference appears to be that the formation of ethylene and of acetylene is attended by a very slight evolution or even by an absorption of heat; the compounds when formed retain much energy, resembling in some degree simple bodies, and in their combination with other bodies, positive work is performed with disengagement of heat; the formation of formene, water, carbonic dioxide, and ammonia is effected with great disengagement of heat, and their combination with hydrocarbons with elimination of hydrogen, if occurring at all, will be accomplished with difficulty from the negative work of the direct affinities, and the absorption of heat attending the elimination of hydrogen; therefore in these cases it is necessary to call in the aid of bodies possessed of powerful affinities to supplement the negative work, and to perform the reactions by some indirect methods.—(*Bull. Soc. Chim. Paris*, 1867, 122.)

Periodic Acid, its Basicity.—C. G. Lautsch has examined a number of periodates without being able to give decisive evidence on this point. He is inclined to the opinion that this acid is pentatomic and tribasic, notwithstanding that a difference between atomicity and basicity has not yet been established in the case of any mineral acid. The question might be conclusively answered if it were possible to introduce into the molecule of the acid alcohol and organic acid radicals, but the oxidising power of the acid is so great that it is doubtful whether it is possible to effect this replacement.—(*Journ. prakt. Chem.* c. 65.)

Cobalt and Nickel, Equivalents of.—Dr. E. v. Sommaruga. The determination of the equivalent of cobalt was performed on Gibb's and Genth's purpureo-cobaltic chloride; this salt was dried perfectly by many hours' heating at 110°, weighed, heated till the ammonia, ammonic chloride, and water were wholly expelled. The resulting very hygroscopic cobaltic chloride was then reduced by hydrogen; the metallic cobalt was weighed, and gave a mean of seven determinations 29·965, maximum 30·009, minimum 29·916.

The nickelo-potassic sulphate was used for the determination of the equivalent of nickel. To prepare this salt, commercial nickel was dissolved in dilute sulphuric acid, to which nitric acid was occasionally added; a quantity of potassic sulphate, insufficient to combine with all the nickelic sulphate, was added to the filtered solution; the solution was evaporated to crystallisation, and the crystals, after washing out the nickelic sulphate, were recrystallised several times. The final product worked on still retained traces of cobalt, but no other impurity. The crystals were dried at 100° and weighed; the sulphuric acid was determined as usual, and the equivalent of nickel calculated from the weight of baric sulphate. The mean of six experiments was 29·013; maximum, 29·079; minimum, 28·911. The proximity of these numbers to those obtained by R. Schneider from different experimental bases supports the author in assigning to cobalt the equivalent 30, to nickel 29.—(*Sitzungsber. Akad. Wien*, June, 1866.)

Vapour Density, Determination of.—R. Bunsen. As the omission of one minute detail would, in performing determinations by this method, render the result worthless, an abstract of this wonderful paper would be of little value, and no abstract could give an idea of the astonishing delicacy of the operations described; we therefore refer readers to the original, remarking that with carbonic dioxide, six experiments, in each of which less than ·35 gramme was employed, a mean 1·527, maximum 1·529, minimum 1·525, were found. Regnault, working on 19 grammes, found 1·529.—(*Ann. Chem. Pharm.* cxli. 273.)

Fatty Acids, Chloro-derivatives of (C=12).—Dr. W. Schlebusch. Hypochlorous acid does not unite with fatty acids, but introduces chlorine into their molecule; the acetic acid chloro-derivative is difficult to obtain; valeric acid gives chlorvaleric acid, described by Clark and Fittig. Valerolactic acid and its baric, cupric, and argentic salts are described. Butalanine $C_5H_{11}O_2N$ was obtained by heating the crude chlorvaleric acid with absolute alcohol saturated with ammonia. After a few hours' exposure in sealed tubes to 120°, the solution was evaporated to expel ammonia and alcohol, heated with baric hydrated oxide to decompose ammonic chloride, freed from baric salts by sulphuric acid, and evaporated to crystallisation. Butalanine combines with acids. With chlorhydric acid transparent plates are formed.—(*Ann. Chem. Pharm.* cxli. 322.)

Carminic Acid (C = 12).—H. Hlasiwetz and A. Grabowski. Carminic acid, when boiled with dilute sulphuric acid, splits into carmine red and sugar; the latter reduces Trommer's solution, and gives Pettenkofer's reaction, but neither ferments nor acts on polarised light; traces of it are dissolved by alcohol. Dried at 50°, its formula was $C_6H_{10}O_6$; at 100°, $C_6H_8O_4$.

Carmine red, $C_{11}H_{12}O_7$, is a dark purple amorphous substance, reflecting green light, soluble in water and alcohol, with a fine red color; insoluble in ether. Like carminic acid, it pertinaciously retains traces of phosphates; its alcoholic solution, when treated with alcoholic potash solution, deposits the whole of the carmine red as $C_{11}H_{10}K_2O_7$, from which the corresponding baric and calcic compounds were obtained. Powerful reducing agents perfectly decolorise the solution of carmine red, but the resulting body could not be separated in a pure state. Fused with potash solution of appropriate strength, carmine red gives oxalic and succinic acids, and coccinin—probably $C_{14}H_{12}O_5$—a body resembling chinon. Its crystals polarise light, are insoluble in water, easily soluble in alcohol, difficultly so in ether. Coccinin dissolves very easily in dilute alkaline solutions, and in such solution is one of the most sensitive bodies to the action of oxygen. The solution is at first yellow, then violet, finally a magnificent purple red. Few bodies give rise to so many phenomena of colour as coccinin.

From the splitting of carminic acid into carmine red and sugar, perhaps Schützenberger's is the nearest to the real formula—probably $C_{17}H_{18}O_{10}$—of that much-investigated body.—(*Ann. Chem. Pharm.* cxli. 329.)

Rufigallic Acid, a Derivative of ($C = 12$.)—G. Malin. Rufigallic acid was fused with potash, and gave among other things a straw-coloured body crystallising in very slender needles soluble in boiling water, in alcohol, and in ether, sparingly soluble in cold water, reacting acid, decomposed by heat; its aqueous solution reduced argentic and alkaline cupric solutions; it did not appear to combine very definitely with anything. Its formula is $C_6H_4O_3$, and its name oxychinone.—(*Ann. Chem. Pharm.* cxli. 345.)

Resins rendered Soluble.—H. Violette. Copal and other refractory resins are soluble in oil of turpentine, &c., if they have been heated for 15—20 minutes to 350—400°, of course in closed vessels. The best way of operating is to heat the resin for a few minutes in an open vessel; 5 or 6 per cent. of water are by this means expelled. The vessel is then closed, and the heating continued. The product gives very excellent varnishes. To avoid the necessity of heating the varnishes made as described, in order to brighten them, the oil, &c., which it is intended should be used, may be heated together with the resin. The product then simply needs dilution.—(*Ann. Chim. Phys.* [4] x. 310.)

Phosphorous Acid ($O = 16$).—Rammelsberg. The examination of compounds of phosphorous acid with dyadic metals leads to the conclusion that this acid exists in three states, corresponding to the ortho-, pyro-, and metaphosphoric acids. Thus the (K', Na', Am'), together with the (Pb'', Cu'', Cd'', Mn'', Co'', Ni''?) salts, which may respectively be typified by HR'_2PO_3 and $HR''PO_3$, point to $\left.\begin{matrix}H_2\\H(PO)''\end{matrix}\right\}O_2$, corresponding to metaphosphoric acid. The (Ba'', Sr'', Ca'', Ni''?, Zn''?) salts give $H_5P_2O_7$, otherwise $\left.\begin{matrix}H_6\\2H(PO)''\end{matrix}\right\}O_5$, corresponding to pyrophosphoric acid, and the magnesic salt, though less decisively, indicates $\left.\begin{matrix}H_4\\H(PO)''\end{matrix}\right\}O_3$, corresponding to orthophosphoric acid. An ethylic salt, in which the hydrogen is wholly replaced by ethyl, is represented by $\left.\begin{matrix}2(C_2H_5)\\C_2H_5(PO)''\end{matrix}\right\}O_2$. It is to be observed that whilst the acid radical in phosphoric acid is triadic, that in phosphorous acid, having one bond saturated by H, is only dyadic $H(PO)''$; similarly the acid radical of hypophosphorous acid is only monadic $H_2(PO)'$.—(*Monatsber. Berl. Akad.* Aug. 1866.)

Ethylic Chloracetate, Action of Ammonic Carbonate on.—W. Heintz. The acids of the lactic series possess at once the functions of acids and alcohols, their basicity remaining unaltered by the replacement of hydrogen by acid radicals; and as under the influence of dyadic metals two molecules of acid will unite in order to furnish two replaceable atoms of H basylous, so under the influence of acid radicals should two molecules unite to furnish H_2 chlorous. The preparation of ethylic succinyllactate proves the correctness of this view. Dyadic carbonyl not having been used in a similar reaction, an attempt was made to effect this molecular combination by means of sodic carbonate, but the product was too small to be useful. Ammonic carbonate was therefore employed, it seeming likely that its volatility would assist the reaction, but an examination of the products obtained showed that carbonic acid did not intervene in the reaction which really did occur, the result of the experiments being that ethylic tri-, and probably dis-, glycolamidate were produced.—(*Ann. Chem. Pharm.* cxli. 355.)

Cupric Persulphide ($Cu = 63{\cdot}5, S = 32$).—A. Gescher. Bloxam's body $Cu_2\ (NH_4)_2S_7$ was prepared by making solution of ammonic persulphide of such strength that a sample of it, mixed with an ammoniacal solution of cupric sulphate, deposited on standing red crystals quite free from black cupric sulphide. The right strength being attained, the solutions were mixed in bulk. To the crystals so obtained the formula $2CuS_3 + (NH_4)_2S$ is attributed.—(*Ann. Chem. Pharm.* cxli. 350.)

Aromatic Monamines give rise to Acids richer in Carbon.—A. W. Hofmann. The principal product obtained by distilling one molecule of oxalic acid with two molecules of aniline is phenylformamide, but secondary actions give rise in addition to carbonic dioxide; from the proportions one molecule of oxalic acid and one molecule of aniline, a crude product was distilled containing cyanhydric acid; heated with concentrated chlorhydric acid, and distilled, this crude distillate gave off with the steam an oily body of aromatic odour, which, when boiled with solution of soda, partly dissolved with disengagement of ammonia (resulting from decomposition of diphenylamine); the addition of chlorhydric acid to the alkaline solution produced a precipitate of benzoic acid, the argentic salt analysed, showing that the oily liquid with aromatic odour contained benzonitrile. This body evidently results from splitting of phenylformamide into water and benzonitrile.

The production is an analogous reaction of toluylic acid from toluidine, and a superbly crystalline acid, $C_{11}H_8O_2$, from naphthylamine, proves the generality of the reaction.—(*Comptes R.* lxiv. 387.)

Reactions, General Conditions of.—M. Berthelot considers that a chemical reaction which is capable of setting free a notable quantity of heat will necessarily and directly occur whenever the following conditions exist:—1. The reaction is one which reaches its limit within a very short time from its commencement; this condition is fundamental. 2. The reaction is one which begins without foreign aid at the temperature at the commencement of the experiment; reactions excluded by this condition act in conformity with the principle enunciated, if they are caused to set in, either by raising the temperature or by other means. 3. The parent substances and the products possess similar functions. He is of opinion that the inverse reactions of iodhydric acid and argentic chloride might be foreseen from the basis of this general principle, and that the analogous action of iodhydric acid on potassic chloride, which he has experimentally verified, is a further proof of the correctness of his view.—(*Comptes R.* lxiv. 413.)

Glass.—L. Clemandot. A sample of glass was made from silica and soda, free from lime, the silica being greatly in excess; after fusion at a very high temperature, and while fusing, a portion was taken out; this portion has remained perfectly unaltered; the remainder, after slow cooling in the crucible, became devitrified. Excess in the proportion of any one ingredient is likely to render glass devitrifiable. The most stable glass is that one which is most complex in composition—that is, which contains the greatest number of bases.—(*Comptes R.* lxiv. 415.)

MISCELLANEOUS.

Conversazione at the Pharmaceutical Society.—The annual gathering of the members of this Society and their friends took place on the evening of Tuesday last. The attendance was very numerous, and included several visitors distinguished in various branches of science. During the evening Mr. Baines gave a descriptive lecture on his geographical and ethnological explorations in the interior of Africa, profusely illustrated with photographs and transparencies, which were projected on a screen from a magic lantern. The objects of interest to chemists were very numerous, and amongst other novelties included large masses of fused and forged platinum, magnesium in various forms, and pure hydrate of sodium, by Messrs. Johnson and Matthey; Mr. Beane's valuable ozone generator exhibited at work, as used for the decolorisation of sugar, by Mr. Ladd; Professor Wheatstone's magneto-electric machine; specimens of the new porcelain standard yard and metre, as adopted by the International Association for obtaining a uniform decimal system of measures, weights, and coins, exhibited by Mr. Casella; and a new form of gas-engine, and a new hot-air engine. These last two are sufficiently interesting to deserve a more extended notice. The gas-engine is the invention of M. P. Hugon, and is the first we have seen that requires no electricity. This engine may be worked the whole day without any supervision whatever, and requires nothing but turning on and lighting the gas to set it in full work. When once started it may be locked up and left going day and night without stopping. There is so little danger from its use that its presence does not affect insurance. The expense of the power is said to be about one halfpenny per man per hour, and, used in this form, the employer possesses the advantage of discharging the labour at any moment, and of only paying for it whilst actually required.

The hot-air engine is based upon the fact, long known to scientific engineers, that the most economical mode of obtaining power from heat is by its direct application to the expansion of air, or other permanent gases, rather than by that of steam or any other vapour. The hot-air engine now described differs from the so-called "caloric engines" in several essential particulars as to its construction, so that it is free from those defects which have hitherto prevented the practical carrying out of the caloric theory. In this engine the motive power, instead of being derived from the expansion of air heated in a separate generator, as in former engines, is produced by the expansion of air heated by contact with the fuel itself, and, in addition to this source of the power, by the action of the expansive force of the gaseous products of the combustion of the fuel, which heretofore have been permitted to escape into the chimney without being in any way utilised in the production of power. This result is accomplished by placing the fuel in a grate which can be hermetically closed, and forcing the air required for combustion into it by means of an air-pump worked by the engine itself, so that no part of the heated air of the gases produced by the combustion of the fuel can escape without passing through the cylinder, and there doing duty in the production of force. It is obvious that by such an arrangement the employment of separate iron generators for the purpose of heating the air is dispensed with, and that thereby one of the chief difficulties of the old caloric engine is avoided; for in the hot-air engine the fuel is contained in a fire-clay furnace surrounded by an air-tight iron casing, which in this way is entirely protected from injury. The fuel, which may be anthracite, smokeless coal, or coke, is thus burned under pressure with great regularity, and with the production of a uniform temperature, and at a rate exactly proportionate to the duty the engine is called upon to perform, thus avoiding all waste of fuel—a result which has not been attained with any form of engine yet introduced.

The heated air, together with the gases produced by the combustion of the fuel, pass from the fire-box directly into the cylinder, so that every unit of heat produced is converted into force. The piston consists of a hollow plunger, to which the piston-rod is attached; the packing is placed around its upper circumference, where the heat is so moderate as to permit of efficient packing and lubrication. By means of an air-pump worked by the piston, a supply of air is forced into the grate. It here comes in contact with the fire, and a portion of it, in maintaining combustion, combines with the carbon, producing carbonic acid, &c.; while another portion of the air in excess takes up heat, and is thereby expanded. The mixed heated air and gaseous products of combustion speedily accumulate such an amount of expansive force as to set the engine in motion, by pressing on the piston. At the end of the stroke the expanded gases escape by the waste-pipe, which may be connected by a common stove-pipe with an ordinary chimney. Each upward stroke of the piston produces a downward corresponding stroke of the air-pump, and forces a fresh charge of cold air into the grate to maintain the combustion of the fuel, thus keeping up a continual supply of heated air and gaseous products. The power is increased or diminished by dampers, which pass the air through or over the fire, according to the amount required.

The chief advantages of the hot-air engine will be found in the very important facts, that there is not the most remote danger in its use. The furnace is perfectly insulated, so that all risk of fire is entirely avoided, and the presence of water, whether in large or small quantity, is dispensed with; so that this engine can be employed under circumstances where it would be impossible to use a steam-engine. Either of these engines will be found invaluable in the pharmaceutical laboratory or physical workshop. Each possesses advantages peculiar to itself, but both are free from the drawbacks attending the use of steam-engines, as they require no skilled labour, no water, do not increase insurance, make no dirt, and are entirely free from danger.

Alum Crystallisations over Fresh Flowers.—Make baskets of pliable copper wire, and wrap them with gauze. Into these tie to the bottom violets, ferns, geranium leaves, chrysanthemums—in fact, any flowers except full-blown roses—and sink them in a solution of alum of one pound to the gallon of water, after the solution has cooled, as the colours will then be preserved in their original beauty, and the crystallised alum will hold faster than when from a hot solution. When you have a light covering of distinct crystals that cover completely the articles, remove carefully, and allow them to drain for twelve hours. These baskets make a beautiful parlour ornament, and for a long time preserve the freshness of the flowers.—*W. P. Creecy*, in the *Am. Journ. Pharmacy.*

Death of Walter Crum.—Many of our readers will hear with regret of the decease of Mr. Walter Crum, which took place on the 4th inst., at Thornliebank. Mr. Crum had been for more than twenty years a Fellow of the Royal Society. His papers, chiefly on subjects connected with calico-printing, were numerous, and bore the stamp of great talent and originality; we may especially mention his researches on Indigo, on the Acetates of Alumina, on Mordants in Dyeing, on Cotton-fibre, &c. By his death the Chemical Society loses one of its original Fellows and a respected Vice-President.

Civil List Pensions.—The following pensions on the Civil List have been recently granted:—100*l.* a year to Lady Harris, widow of Sir William Snow Harris, in consideration of her husband's valuable invention of the system of lightning conductors. 100*l.* a year to the Rev. Miles Joseph Berkeley, on account of his eminent services as a botanist, to practical horticulture and agriculture. 95*l.* a year to George Cruikshank, Esq., on account of his great merit as an artist.

Scientific Lecturing pays well in America. Professor Agassiz lately delivered a course of lectures under the auspices of the New York Association for the Advancement of Science, on the Natural History of Brazil, for which he demanded and was paid 500 dollars each, or 3,000 dollars for the course of six lectures. Taking the time he devoted to each lecture—that is to say, an average of one hour and forty minutes—it thus appears that he received five dollars a minute for every minute he spoke. It appears, however, that the association which engaged his services did not lose. —*Pall Mall Gazette.*

Extraction of Indium from the Products of the Roasting of Blende.—The flue dust which condenses in the chimneys of the zinc works of Goslar contain indium. The author has operated on 100 kilogrammes of this dust, which contains about one part of oxide of indium in 1000. To extract this metal, boil the deposit for half an hour with hydrochloric acid, and digest the clear liquid with pieces of zinc for six hours at the ordinary temperature. There is then deposited a black metallic powder, which is washed with water, and which contains copper, arsenic, cadmium, thallium, and indium. By boiling this with a concentrated solution of oxalic acid, a solution of cadmium, thallium, and indium is obtained; the latter is precipitated by ammonia, and the precipitate is then boiled with ammonia and afterwards with water, until the washings contain no more thallium. The oxide of indium is then almost pure, and only contains traces of iron, from which it may be freed by Dr. Winckler's method given in the Chemical News, vol. xiv. p. 157.—*M. Boettger*, in the *Journal für praktische Chemie*, t. xcviii. p. 26, No. 9.

Determination of Iodine by Means of Chloride of Silver.—To determine the iodine contained in organic hydriodates, M. Kraut digests the solution for several minutes with a known quantity of recently precipitated chloride of silver; the increase of the weight of the chloride of silver is in proportion to the amount of iodine. This method has the advantage of not altering the substance beyond the removal of its iodine, which is replaced by chlorine. The process is very useful in many cases.—*Zeitschrift für analytische Chemie*, iv. 167.

Analysis of Earth eaten in Borneo.—Some few years ago the manager of the Orange-Nassau colliery, near Zandjermasin, in the Island of Borneo, found that many of his workpeople (natives) consumed large quantities of a kind of clay; a sample of this material was forwarded to Batavia for analysis, and the following is the result in 100 parts:—

Pitcoal resin (organic matter volatile at red heat)	15·4
Pure carbon " " "	14·9
Silica " " "	38·3
Alumina " " "	27·7
Iron pyrites " " "	3·7
	100·0

We remind our readers that the eating of clay is a custom to which savages—or, at least, human beings of a very low degree of development—are freely given in various parts of the world. No other analysis of any of the substances used as such have been made, or at least, if made, they have not been published. The resident military medical officer at the above-named colliery is strongly inclined to consider it the duty of the manager to eradicate and discountenance this habit of the workmen, as it appears to injure their health.

Obituary.—It is with regret that we announce the death of Mr. Hippolyte Baillière, the well-known scientific publisher, which took place on Saturday last at his residence, 219, Regent Street. Mr. Baillière's illness has been long and painful, and for some time past his sons have taken a very active part in the practical management of the business. The late Mr. Baillière's energy and talents have caused his name to be known and respected in many of the capitals of Europe and America.

Quinine.—The *Homeward Mail* reports a singular affair which has just occurred at Calcutta. Under the Indian Patent Act, every exclusive privilege must cease if the Governor-General of India in Council shall declare that the same is generally prejudicial to the public. This has accordingly been done in the case of a petition filed by W. G. M'Ivor, who wishes for a patent for an alleged new invention for producing and preparing the different species and varieties of cinchona bark for the manufacture of quinine, quinidine, cinchonidine, and other alkaloids.

Estimation of Silver in a Metallic State.—According to M. Classen, silver is wholly precipitated by cadmium; when dealing with a nitric solution of silver, evaporate to dryness in the presence of sulphuric acid, dissolve the sulphate of silver in boiling water, plunge into it a plate of cadmium, and the reduction of the silver takes place at once. The silver is deposited in a compact mass, easily washed with water; as it may contain a little cadmium, boil it in the acid liquid until no hydrogen escapes; wash it until the water contains no sulphuric acid; then dry, and calcine; the silver, at first a black grey, takes the metallic lustre; it may then be weighed:—the results are very exact.

NOTES AND QUERIES.

Transformation of Naphthalin into Benzoic Acid.—Sir,—Can you inform me where I can obtain a formula for this process, mentioned in your number, 385, page 197, in Notes on the Paris Exhibition?—Sydney Hall. Swansea.

Nitro-benzol.—Sir,—Can you tell me how nitro-benzol can be obtained colourless and free from the tarry smell which usually accompanies it?—A Manufacturer.

Depositing Platinum Electrolytically.—Sir,—Will any of your correspondents tell me what is the best solution and battery power to be used for depositing a coherent film of platinum on brass? I should like it to be strong enough to resist liquid acids, but if this is impracticable, a resistance to acid vapours will suffice.

Chinese Blue.—Sir,—A friend of mine is desirous of obtaining a good receipt for making Chinese blue. He is a large consumer, and wishes to manufacture for himself and another house. He has made it, but not satisfactory in comparison with London manufacturers. He would of course pay handsomely for it. Would it be possible to obtain this? and through what channel?—R. H. W., Manchester.

Purified Shellac.—Sir,—In reference to the suggestion in your last number, I am the inventor of a new method of bleaching and purifying shellac, not by chlorine or its homologues, or by any injurious agent; it is in a state of solution in methylated spirits, and is applicable to gilt work, &c., not injuring anything it is applied to. To any one with a small capital, or in the above way of business, my services would be of value. I am not a thorough chemist, but possess a slight knowledge sufficient for the above. I cannot afford to advertise much, and think this would come under the head "Notes and Queries."—E. M. Nash.

Caramel Colours.—Sir,—Can any of your numerous readers tell me the best way to make these? I am a vinegar manufacturer, and use a considerable quantity for giving a dark colour to the vinegar. The manufacture is kept a profound secret by those few houses who make a specialty of it. I have made several attempts, but have hitherto been unsuccessful.—E. A. Glasgow.

Colours from Caramel.—Sir,—Perhaps the following information may be of use to your correspondent:—The secret consists in using glucose and heating it with an alkali. For vinegar, carbonate of ammonia is required, as a fixed alkali produces turbidity. 120 pounds of glucose require 6 pounds of carbonate of ammonia and 6 pounds of water. Heat together in a metal boiler till the glucose is of the desired colour, keeping the mixture well stirred. Then add 30 or 40 pounds of warm water poured in a thin stream.—F. Thompson.

Glass Drilling.—A correspondent, D. F., informs us that the process for working glass with files, drills, or other tools of steel, moistened with dilute sulphuric acid, as given by Dr. Lunge in the last number of the Chemical News, was the subject of a patent taken out by Maudsley some years back.

Nitro-benzol.—Sir,—In reply to "Manufacturer," I beg to inform him that I have prepared nitro-benzol nearly colourless, and with a pure fragrant odour, by distilling it much below its boiling point in a current of steam. The first portions, which contain benzol, &c., are to be rejected.

Light Coal Oil.—Sir,—Have any of your readers tried a plan of mixing the light oil obtained from coal tar with a solution of chloride of lime, and submitting the mixture to distillation? If so, what changes have been noticed, and what was the action on the sulphur compounds? —M.

Calico Printing.—Sir,—I have spent over three years in trying to improve various colours now in use by calico printers and dyers. I shall be glad if you could assist me in obtaining a little ready money for the following important discovery:—I can print on cotton goods a mordant that will produce a perfectly fast mauve, with, or at the same time as, garancine work, more fast and bright than any produced previously. I can dye all aniline colours faster and brighter than they have ever been done, and at a much less expense, on any kind of fabric. I can also produce the same shade of colour on mixed goods at one operation, and which is both cheap and simple. I will render every explanation necessary to any one applying through you or your valuable paper, and give any security and guarantee.—J. K. M.

Calico Printing.—Sir,—Referring to your note upon calico printing in last week's publication, I shall have pleasure in arranging with "J. K. M." a permanent system of remuneration for the advantages he names, which, if reliable, will stimulate the aniline colour trade. If you will let me have the address of "J. K. M.," I will at once communicate with him.—R. E. B., Manchester.

Caromel Colours.—Sir,—I have noted the correspondence respecting caramel colours in the Chemical News, and I should be glad to learn where glucose can be obtained in manufacturing quantities. There was a "Glucose and Caramel Company" in existence some time since, but it is now defunct; and I am therefore at a loss where to obtain it, and cannot spare the time for making it.—J. W.

Map Varnish.—Sir,—I want to prepare a good map varnish which will dry rapidly. If any of your correspondents will kindly instruct me in its preparation through the medium of your valuable section, "Notes and Queries," they will confer a favour upon me.—J. S.

Artificial Teeth.—Sir,—Within the last few years some improvements have been made in the manufacture of artificial teeth, by which they are rendered less brittle. I am anxious to find directions for their preparation, and shall be happy to pay any person who will assist me in this matter.—F. T., Leeds.

Crystallisation of Chromates.—Sir,—During the crystallising of bichromate of potash, a coating of light lemon-coloured crystals formed on the front of the bichromate. These crystals did not, however, appear till the crystals of bichromate had almost done forming. The mother liquor at the time was about six or eight degrees warmer than the surrounding atmosphere. If the liquor was allowed to remain in the crystallising pans until perfectly cold, the crystals referred to would increase to four or six inches in thickness. The form of these crystals was an oblique four-sided prism. Now, this did not appear from want of sulphuric acid; if that was the case, the crystals would have been green. The amount of potash required to decompose the oxide of chromium was calculated correctly and added. Has any of your readers who may be acquainted with the manufacture of bichromate of potash ever noticed the formation of the crystals named, and to what cause can their appearance be traced?—H.

Map Varnish.—Sir,—J. S. will find that he can make a very good varnish for covering over architectural and mechanical drawings, maps, &c., by dissolving one pound of white shellac, a quarter of a pound of camphor, and two ounces of Canada balsam in one gallon of alcohol.

Map Varnish.—Sir,—I beg to place the following recipe at the service of "J. S.," who wishes to know how to prepare a good, quick-drying map varnish:—Thin down with turpentine Canada balsam, and add one-fourth of the bulk of quick-drying pale copal varnish; lay on smoothly with a flat camel-hair brush, and let the map lie flat for a few hours.—Thos. Bournes.

Artificial Teeth.—In reply to the inquiry from F. T., Leeds, in our last number, we have received several letters. They have been forwarded as requested.

Chinese Blue.—Sir,—Will you oblige me by notifying that you wish to receive communications for a subscriber on the subject of Chinese blue from the same or others who replied to R. H. W., of Manchester? Information of value would be paid for.—Wm. Schofield.

Palm Oil.—Sir,—If any of your correspondents will inform me how much chrome is necessary to bleach a cwt. of palm oil, they will confer a favour on yours, &c., Milo.

Santonine.—Sir,—Can any of your readers favour me with some good directions for mounting santonine for the microscope so as to obtain good polarizing crystals?—F. Cooper.

Letters are waiting at our Office for F. T., Leeds; R. E. B., Manchester; H. P. Meaden; J. K. M.; Manufacturer.

ANSWERS TO CORRESPONDENTS.

⁂ All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E. C. *Private* letters for the Editor must be so marked.

⁂ In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

D. H. W.—M. Stas's researches have appeared in the *Proceedings of the Royal Academy of Belgium*. Inquire at Asher's.

G. M. E., Brighton.—The instrument is not yet complete. A full description will appear in the Chemical News as soon as it is in operation.

M. Mond's Process for the Recovery of Sulphur from Alkali Waste.—The inventor has drawn our attention to the description of this process given by our Paris correspondent in our number for April 12, p. 183, as not being sufficiently clear. After saying that the process consists in forcing a current of air into the waste in order to oxidise it, and then lixiviating, the description should continue, "The solution is then drawn off, and air again forced into the waste, the mass again lixiviated, and the same treatment repeated a third time. The vats are so arranged that the liquor is allowed to run from one vat into the other in order to obtain it as concentrated as possible. The whole of these operations can be performed in from sixty to seventy-two hours." In the subsequent description, hyposulphite of lime should have been spoken of, instead of hyposulphite of soda. M. Mond says that the process is being successfully employed at many alkali works in England, amongst others at Messrs. Hutchinson and Co.'s, Widnes.

W.—Crucible is derived from the Latin *crucio*, to torture or twist.

Townsend, Hook and Co.—The address shall be sent. The author is preparing an article on the subject for these pages.

W. Becket.—The syrup of orange and quinine appears likely to be of value in cases where orange wine and quinine would be injurious to the system.

Constant Reader and *Another Person.*—Sunlight shining on a fire will not put it out nor prevent combustion. The explanation of the popular opinion on this point is, that the light of the sun is so immeasurably superior to that of the fire, that the latter appears to lose its brilliancy when sunlight falls on it, and to an ordinary observer would seem dead.

T. S.—We should be pleased to receive the information in a form fit for publication.

M. M. Soo.—The animal matter may be removed from the sections of bone by soaking them in caustic potash. The alkali must be well washed out before mounting the sections. Canada balsam is best for the latter purpose.

M. Jenkins.—What is usually known as queen's metal is an alloy formed of two parts of tin and one part each of lead, antimony, and bismuth.

A Student.—The term "wad" is applied to two distinct minerals. It generally means an ore of manganese mixed with iron; but in Cumberland the term is applied to plumbago.

A. K.—Tetradymite consists of sulphide and telluride of bismuth with impurities. Its name, however, is not derived from the fact of its being composed of four elements, but from its occurrence in quadruple crystals.

Clericus.—Chloroform is, perhaps, the best substance you can use for removing paint stains from oak. You must remember that it will likewise attack the varnish.

James Y.—The term iodide of calomel is retained in American pharmacy for a mixture of iodide and chlorides of mercury, prepared by mixing iodine with calomel. According to the same barbarous nomenclature, there is a biniodide of calomel.

Butter.—You are mistaken in supposing that only rancid butter contains butyric acid. Fresh butter contains a compound of butyric acid with glycerin, which is inodorous; and it is to the decomposition of this compound on standing, by which butyric acid is set free, that the flavour of rancidity is due.

A Student will find full information on the subject of the atomicity of radicals in Wurtz's "Introduction to Chemical Philosophy," page 104, *et seq.*

Kappa.—You will find all you require in Griffin's "Chemical Handicraft."

P. McPherson.—Heavy hydrocarbon oils containing no naphtha are convertible into oils of the naphtha series under the action of heat.

An Old Subscriber.—The lecture referred to is published in the *Journal of the Chemical Society*. Richardson and Watts's "Technology" gives an excellent account of the alkali manufacture.

Communications have been received from Pritchard, Burden, and Co.; S. Hall; Rev. B. W. Gibsone; T. Davies; F. M. Sargeant; J. Pratt; J. Tomlinson; M. Burton; H. Gillman; J. Hargreaves; J. W. Swindells; W. T. Suffolk; W. M. Bywater; Lloyd Smith; George Dutton (with enclosure); H. B. Condy; John Hull; Charles A. Wright; T. B.; Wotherspoon and Co.; G. M. E.; Sir W. Thompson (with enclosure); Geological Society (with enclosure); Dr. H. W.; F. Webb; G. Penny; Dr. S. Muspratt (with enclosure); R. H. W.; Sir H. J. Brownrigg; The Quekett Microscopical Club (with enclosure); J. Glen; A Constant Subscriber; G. A. Keyworth; L. Mond; J. H. Swindells; A. Jaeger; T. Sherlock; J. Kenyon; R. Hulse; J. C. Bell, F.C.S.; G. Thompson; Lewis, Ash, and Co.; A Subscriber; A Constant Reader; James Browne and Son; E. Tate; Messrs. Huskisson and Son; P. Squire; Johnson and Sons; Another Person; Gaskell, Deacon, and Co; Allhusen and Son; May and Baker; J. R. Hass and Co.; W. Beckett; Townsend, Hook, and Co.; S. Mellor; Dr. Adriani; F. Field; T. Sherlock; G. F. Rodwell; W. Webb; Price's Patent Candle Company; J. Sullivan; Lloyd Smith; the Walker Alkali Company; T. Parkins; C. Ogleby and Co.; J. Muspratt and Sons; J. F. MacFarlan and Co.; Davey, Yates, and Routledge; Allen and Hanbury; J. J. Vaughan; Professor B. Silliman (with enclosure); F. C. Calvert; Geological Society (with enclosure); Clericus; Henry Charlton; R. E. B.; J. V.; W. Gossage; Editors of Journal of Mining: William Schofield; E. THE CHEMICAL NEWS.
Vol. I. No. 2. American Reprint.

IDEAL CHEMISTRY.

On Thursday next the Fellows of the Chemical Society will assemble at Burlington House to hear a lecture by Sir Benjamin Brodie on the new Chemical Calculus. The subject is perhaps the most abstruse which has ever been brought before the Society, and it has, therefore, been considered advisable for us to give in the present number a slight outline of the methods of reasoning adopted by the learned author, as set forth in the paper* which has just appeared in the *Philosophical Transactions*.

The memoir, of which the first part is the subject of this article, will mark a new epoch in that branch of chemical science which relates to the symbolic expression of facts. The complete paper is not yet published. The present part, which was read before the Royal Society on May 3, 1866, when it attracted the liveliest attention, and some little discussion from the chemists present, relates to the construction of chemical symbols. In the second part the author proposes to treat of the theory of chemical equations, which is intimately connected with the general processes of chemical reasoning, and especially with the consideration of the nature of that event which is termed a chemical change, of which a new analysis will be given founded on its symbolic expression. In the third part it is intended to consider the principles of symbolic classification, and the light thrown by this method upon the origin and nature of the numercial laws which limit the distribution of weight in chemical change.

The author mainly confines himself at present to the discovery of a system of symbolic expressions by which the composition of the units of weight of chemical substances may be accurately represented, and which may hereafter be employed for the purposes of chemical reasoning. This problem is of a perfectly real nature, admitting, where the experimental data are adequately supplied, of only one solution; and the discussion of this question involves the consideration of the fundamental principles of symbolic expression in chemistry.

In the first section, considerable attention is devoted to the definitions, and the various terms used have definite significations attached to them. "Ponderable matter" and "a chemical substance" require no explanation, but the expression "a weight" is used in a special sense. In this discussion every chemical substance, simple or compound, is exclusively regarded as a *weight* of matter. Its form, condition, or state is disregarded, and the only property with which the chemist has here to do is the transformation of the weights of matter, and the laws of the composition and resolution of these weights. The term *a weight* is used, therefore, in a concrete sense, as when we speak of "a box of weights," and call one of the pieces of metal in the box "*a weight*" of platinum or brass. In just this sense, Sir Benjamin Brodie speaks of *a weight* of water, of oxygen, of sulphur, etc., excluding all other forces but that of gravitation.

A "single weight" is a weight of any portion of matter regarded as one object. The matter making up this weight may be simple or compound, and, if the latter, chemically combined or not. So long as it is considered as one object, it is a single weight.

A "group of weights" is constituted of any number of single weights.

Between two portions of ponderable matter (two "weights") there may be *equality* and *identity* as regards weight. These terms require fuller explanation. Take a *weight* of water—a gramme, for instance—and apply heat to it; it increases in bulk; it becomes a gas; and at a still further elevation of temperature it is resolved into its components, oxygen and hydrogen. But throughout all these profound physical and chemical changes, its action on the balance does not vary. Now, there is the relation of *equality* of weight between a gramme of water and a gramme of oxy-hydrogen gas, as there is between a gramme of water and a gramme of lead. But the gramme of water is connected with the gramme of its component gases by another relation, that of continuity of existence, or *identity*, which does not exist between the gramme of water and the gramme of lead.

A compound weight is here defined as a single weight of which the whole is identical with two or more weights. Such weights are termed the components of the compound weight, which is said to be composed of them. A "simple weight" is a weight which is not compound—that is, which has only one component.

It is necessary to select a "unit of ponderable matter" which may serve as the common measure of those chemical properties which it is desired to investigate, and in this investigation the "unit" is defined as that portion of gaseous ponderable matter which occupies the volume of 1000 c.c. at 0° C., and a pressure of 760 m. m. of mercury. This volume is called the "unit of space," and the weight of a unit of hydrogen is selected as the standard. The weights of other units of matter can therefore be expressed absolutely in grammes, or relatively in reference to the standard unit of hydrogen.

When a compound weight (*e.g.*, a weight of water) is resolved into its component weights (*e.g.*, a weight of oxygen and a weight of hydrogen), the weight is said to be "distributed." The same expression is used in reference to the converse operation of synthesis. The meaning of the term "undistributed weight" follows from the above. A distributed weight is necessarily a compound weight, and an undistributed weight must be regarded, in respect to the events under consideration, as simple, although under other circumstances it might prove to be a compound weight.

A chemical operation is defined as an operation performed on the unit of space of which the result is *a weight*. These chemical operations are represented by symbols x, y.... The symbol $+$ is the symbol of the operation by which one weight is added to another to constitute with it one group. The symbol $-$ represents the removal of a weight from a group of weights. The symbol $=$ is the symbol of identity. The symbol $x + y$ represents a group constituted of the two weights A and B; $x + x$ or $2x$, is the symbol of two weights A; and $x - y$ is the symbol of the weight A without the weight B. The symbol 0 is the symbol of a group in which no weight appears, and which has had its origin in the several performances of the operations x and $-x$; so that $x - x = 0$, and $0 + x = x$. The symbols $+$, $-$, and $=$ are here used in a sense analogous to their arithmetical meaning. No uniform interpretation has hitherto been attached to them in chemistry.

---

* "*The Calculus of Chemical Operations; being a Method for the Investigation, by Means of Symbols, of the Laws of the Distribution of Weight in Chemical Change*," by Sir Benjamin C. Brodie, Bart., F.R.S., Professor of Chemistry in the University of Oxford.

But the most important feature of the method is the introduction of the symbol xy as the symbol of a compound weight, of which two portions of matter, say A and B, are the component weights. This symbol indicates that we are to perform the operation y upon the unit of space, and then to perform successively upon that *same* unit the operation x, in which respect it differs from the symbol $x + y$, which indicates that the operations are to be performed upon distinct units, the results being different, according as the operations are performed *successively, jointly, severally*, or *collectively*. The symbol xy is the symbol of the *successive* operations x and y; (xy) represents their *joint* operations; $x + y$ represents them operating *severally*; and $(x + y)$ represents the same operations operating collectively. We can thus express with accuracy the various ways in which we conceive of the existence of the same ponderable matter.

The symbol 1 is necessarily contained as a common factor in every chemical symbol, and is the symbol of the common subject of operation, the unit of space. But the unit of space, as above explained, is space without weight, and the symbol 1 is therefore the symbol of "no weight." It is therefore inferred that $0 = 1$. This equation may at first sight appear paradoxical; it need not, however, be a matter of surprise that in the chemical calculus we should have two symbols for "no weight," since in that system the same ponderable matter may be denoted by xy and $x + y$. These different symbols are necessary, as representing the different ways the "weight" or the "no weight" has been obtained. Similarly, the symbol ∞ is to be interpreted as the symbol of the ponderable universe regarded as a whole, and the symbols 1 and ∞ represent in the calculus of chemistry the limits between which the values of all other symbols are comprised.

Now, according to the definition given of chemical identity, two weights are said to be identical which consist of the same weights; hence the weight (or matter) of which xy is the symbol is identical with the weight (or matter) of which $x + y$ is the symbol; and

$$xy = x + y.$$

This equation is the fundamental equation of the Calculus, and from it the properties of the symbols are derived.

After a discussion of the fundamental chemical equations, the symbols of simple weights (which are termed prime factors), and the construction of chemical equations from the data afforded by experiment, the author proceeds to the symbols of the units of chemical substances. One hypothesis is assumed, and that is that the unit of hydrogen is a simple weight. The symbol of this "weight" is expressed by the letter α. The absolute weight of the portion of ponderable matter thus symbolised—that is to say, of 1000 c.c. of hydrogen at 0° C. and 760 m. m. pressure—is 0·089 grm. This is identical with the "crith" of Dr. Hofmann. It is subsequently shown that the units of the elements mercury, zinc, cadmium, and tin may be symbolised in an equally simple manner. The author employs letters of the Greek alphabet as symbols of simple weights. Speaking of this, he says, "It is a mistake to confuse the objects of a symbolic system with those of a 'memoria technica,' and I am inclined to believe that a purely accidental distribution of letters among the weights to be expressed would be the best. In the selection here made, however, I have not proceeded rigidly upon this principle, a certain reminiscence of the name being retained in the symbol, as for example ξ ὀξύς, the θ of θεὶον, the χ of χλωρός, and the δ of ὑδράργυρος. Facility of writing and reading the symbols is, however, far more important than any aid to memory which can be thus afforded, and these points are to be mainly considered. The unit of hydrogen, which occupies a peculiar position as the 'modulus' of the system, is indicated by a special symbol α."

It is known by experiment that 2 units of water can be decomposed into 2 units of hydrogen and 1 unit of oxygen. Now, let

$$\alpha^m\xi^{m_1} = \text{symbol of the unit of water,}$$
$$\alpha \quad = \text{symbol of the unit of hydrogen,}$$
$$\alpha^n\xi^{n_1} = \text{symbol of the unit of oxygen,}$$

where α and ξ are the symbols of simple weights, and m, m_1, n, n_1 positive integers. Then

$$2\alpha^m\xi^{m_1} = 2\alpha + \alpha^n\xi^{n_1},$$

To this is attached the condition that

$$w(\alpha) = 1,$$
$$m + m_1 w(\xi) = 9;$$

from the fundamental equation

$$(\alpha^m\xi^{m_1})^2 = \alpha^2\alpha^n\xi^{n_1},$$

whence

$$2m = 2 + n \text{ and } 2m_1 = n_1.$$

Selecting from the possible solutions of these equations the minimum solution as both necessary and sufficient to satisfy the condition of the equation, we have

$$m = 1, \quad n = 0,$$
$$m_1 = 1, \quad n_1 = 2,$$

which give

Symbol of water, $\alpha\xi$;
Symbol of oxygen, ξ^2;

the relative weights corresponding to the prime factors α and ξ are

$$w(\alpha) = 1,$$
$$w(\xi) = 8,$$

the equation being thus expressed:—

$$2\alpha\xi = 2\alpha + \xi^2.$$

The following table is given of the combinations of the prime factors α and ξ:—

Name of substance.	Prime Factors.	Absolute weight in grammes.	Relative Weight.
	α	0·089	1
	ξ	0·715	8
	Symbol.		
Hydrogen................	α	0·089	1
Oxygen..................	ξ^2	1·430	16
Water....................	$\alpha\xi$	0·805	9
Peroxide of hydrogen......	$\alpha\xi^2$	1·520	17

By a similar process of reasoning, starting from the ascertained facts that the density of sulphur vapour is 32, that of hydrogen being 1, and that the ponderable matter of 2 units of hydrogen is identical with the ponderable matter of 2 units of hydrogen and 1 unit of sulphur, it is shown that the symbol of sulphur is θ^2, and that of sulphuretted hydrogen $\alpha\theta$. The symbol of sulphuric acid $\alpha\theta\xi^4$, and that of pentathionic acid $\alpha\theta^5\xi^6$. Similarly, selenium is symbolised as λ^2, seleniuretted hydrogen becoming $\alpha\lambda$.

In the case of chlorine, which may be taken as the representative of another group of elements, it is ascertained that 2 volumes of hydrochloric acid can be decomposed into 1 volume of hydrochloric acid and 1 volume of chlorine.

Hence, putting $\alpha^m\chi^{m_1}$ as the symbol of the unit of hydrochloric acid, and $\alpha^n\chi^{n_1}$ as the symbol of the unit of chlorine,

$$2\alpha^m\chi^{m_1}=\alpha+\alpha^n\chi^{n_1},$$

and

$$(\alpha^m\chi^{m_1})^2=\alpha\alpha^n\chi^{n_1};$$

whence

$$2m=1+n$$
$$2m_1=n_1$$

and

$$m=1,\quad m_1=1$$
$$n=1,\quad n_1=2,$$

a minimum.

Since the density of hydrochloric acid is 18·25, we have to determine the absolute weight of the simple weight χ,

$$m+m_1w(\chi)=18{\cdot}25,$$

whence

$$w(\chi)=17{\cdot}25,$$

which gives the

Symbol of hydrochloric acid $\alpha\chi$,
Symbol of chlorine........ $\alpha\chi^2$.

We can only briefly allude to the discussion of the symbols of carbon, silicon, and boron. Owing to the impossibility of asertaining the vapour densities of these elements by direct experiment, their symbols cannot be determined in an analogous manner to those of the preceding elements; but inasmuch as we are able to construct numerous chemical equations which connect the vapour densities, of carbon, silicon, and boron with known vapour densities, we are able to determine from these, within certain limits, the symbol of the elements themselves.

From such data as these it is rendered very probable that the symbols of carbon, silicon, and boron are respectively of the terms

$$\kappa^y,\ \sigma^y,\ (\alpha\beta^2)^y.$$

In the case of the elements antimony, bismuth, tin, zinc, cadmium, and silver, different principles of investigation have to be adopted, and their symbols are given according to two or more hypotheses.

The following table of the symbols of the units of certain well-known substances affords sufficient illustration of the method pursued:—

Symbol of iodine	$\alpha\omega^2$
" " bromine	$\alpha\beta^2$
" " nitrogen	$\alpha\nu^2$
" " phosphorus	$\alpha^2\phi^4$
" " arsenic	$\alpha^2\rho^4$
" " chloric acid	$\alpha\chi\xi^3$
" " ammonia	$\alpha^3\nu$
" " chloride of ammonium	$\alpha^3\nu\chi$
" " phosphide of hydrogen	$\alpha^3\phi$
" " oxychloride of phosphorus	$\alpha^2\phi\chi^3\xi$
" " acetylene	$\alpha\kappa^2$
" " alcohol	$\alpha^3\kappa^2\xi$
" " hydrocyanic acid	$\alpha\nu\kappa$
" " cyanogen	$\alpha\nu^2\kappa^2$

We quote the following from the concluding remarks of the author:

"Our conclusions on this point are so remarkable, and so contrary to anticipation, that doubtless we could never trust them but for the simple and exact process by which they are deduced. Now, the conceptions which we form of the nature of the elemental bodies constitute the fundamental theory of the science, for these conceptions comprise and determine every similar conception. The unit of the element hydrogen is here conceived of as a simple weight, and symbolised by the letter α. That, to say the least, this view may be permitted, is proved by constructing the symbols of chemical substances upon this hypothesis. There are, however, certain exceptions, be they real or apparent, in which this mode of expression is impossible." . .

"The unit of the element mercury, and the units of several other metals, such as zinc, cadmium and tin, so far as our imperfect experience extends, appear to be analogous in this respect to hydrogen. But these are the only elements of this simple composition. The units of a second group of which the element oxygen, symbolised as ξ^2, may be taken as a type, and to which belong sulphur θ^2 and selenium λ^2, are composed of two identical simple weights, and the facts of the science do not permit us to assume these units as otherwise composed. Lastly, another group of elements appears in this system of a different and more complex composition, to which group belong the elements chlorine $\alpha\chi^2$, bromine $\alpha\beta^2$, iodine $\alpha\omega^2$, nitrogen $\alpha\nu^2$ phosphorus $(\alpha\phi^2)^2$, arsenic $(\alpha\rho^2)^2$, and, in all probability, numerous other elements. The simplest view which, consistently with the fundamental hypothesis, can be taken of the composition of these elements, regard being had to the total system of chemical combinations, is that they are severally composed of a unit of hydrogen and of two identical simple weights—as, for example, in the case of chlorine, of the simple weight α and two of the simple weights symbolised by χ, so that the elements of this group are to be considered as combinations of elements of the two previous forms respectively."

The author concludes by saying that from these and other equations "we unavoidably have suggested to us as the ultimate origin of our actual system of combinations . . . a group of elements, $\xi, \theta, \chi, \beta, \omega, \nu,$ . . . of the densities indicated by these symbols, and which, . . . we cannot but surmise, may some day become, or may in the past have been, 'isolated and independent existences.' Examples of these simple monad forms of material being are preserved to us in such elements as hydrogen and mercury, which appear in the chemical system, as records suggestive of a state of things different from that which actually prevails, but which has passed away, and which we are unable to restore."

"Such a hypothesis is not precluded to us, but nevertheless we are not to imagine that it is a necessary inference from the facts. So far as the principles or conclusions of this method are concerned, the "simple weights" $\xi, \theta, \chi, \beta, \omega, \nu, \phi$. . . . may be treated purely as "ideal" existences created and called into being to satisfy the demands of the intellect, to enable us to reason and to think in reference to chemical phenomena, but destined to vanish from the scene when their purpose has been served; and the existence of which, as external realities, we neither assume nor deny."

THE CHEMISTRY OF THE FUTURE.

THE meeting of the Chemical Society on Thursday, the 6th inst., will always be memorable in the history of the Society. The importance of the subject which Sir Benjamin Brodie was to bring forward, the fact that eminent physicists and mathematicians had been specially invited to attend, and the probability that the discussion would vie in interest with the lecture itself, justified us in taking unusual means to secure a full and accurate report of the proceedings. We are sure we need make no apology for devoting to this abstruse subject so large a space of our present issue. The report of the lecture, and the discussion thereon, we are justified in speaking of with pride as a veritable *tour de force* of the shorthand writer. Having to deal with a multitude of technical expressions, enhancing the difficulties of his wonderful art, he has given to our readers the very words as they fell from the lips of the speakers; the editorial right of omission or condensation having been very sparingly exercised.

In order to give unabridged and undivided this remarkable report, occupying almost the entire space of an ordinary number, we have been compelled to omit several original articles, and nearly the whole of our foreign and home correspondence; but so that we should not disappoint that numerous class among our readers, who care less for ideal than for positive chemistry, and who value the Chemical News in proportion as it gives them solid facts and useful hints, we have enlarged this number to twenty pages by the issue of a supplement.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Remarks on some Recent Contributions to the History of the Benzole Series,[*] *by* A. H. Church, *M.A., Professor of Chemistry, Royal Agricultural College, Cirencester.*

The more elaborate and exact study of the homologues and derivatives of benzole has revealed many most important facts. Admirable digests of these recent researches will be found in Will's *Jahresbericht* for 1865 (pp. 514 *et seq.*), and in the second volume of Kekulé's *Lehrbuch der organischen Chemie* (pp. 528 *et seq.*). My present object in writing on this subject is twofold—I wish to reassert my own discovery of several new substances and new reactions, and I wish to vindicate the accuracy of some of my experiments against the attacks which they have suffered from one or two foreign chemists.

Twelve years ago my first paper on the benzole series was published. Since that time not only have there been made many additions to our knowledge of hydro-carbons and of the nature of isomerism, but the process of fractional distillation has also been materially improved. Thus it has come to pass that some of my former results I now interpret differently, some I have modified or further developed, some I have corrected in later papers, while some are discoveries now generally acknowledged, and which, in not a few cases, have served as starting-points for the subsequent researches of other chemists. I am compelled, therefore, to attribute, in some measure at least, the hostile criticism of Mr. C. M. Warren and Professor Beilstein to their imperfect acquaintance with the whole series of my published notes and papers. I do not wish to enter into any personal controversy with my critics, and I will not speak of the manner in which my reputation as a chemist has been assailed, but I do feel bound to restate the broad facts concerning the matters in dispute, drawing my data entirely from published sources.

These matters in dispute may be arranged under the three heads of—1. Boiling points; 2. The parabenzole series; 3. Reactions.

1. Boiling Points.—The boiling points I assigned[†] in 1855 to benzole and to the cumole from cuminic acid do not differ widely from those given by Mr. Warren,[*] and even the slight difference that exists is probably due to the methods adopted for correcting the observed temperatures—

	Warren.	Church.
Benzole	80·1	80·8
Bumole	151·1	148·4

With toluole, xylole, and cymole the case is different. Warren places the boiling point of toluole at 110·3°, my determination gave 103·7°,[†] a result not far from that of Glénard and Boudault (106°) and that of Max Dürre. Coal naphtha, there is no doubt, contains a large quantity of a hydrocarbon boiling between 109° and 113°, and seemingly having the composition and properties of the toluole from toluic acid; but this fact is not incompatible with the co-existence of other hydrocarbons of the same formula. I may have placed the boiling point of toluole 6° too low; all I can say as to this matter is that the liquid boiling at 104° gave me every proof of its being toluole.

Xylole was discovered by Cahours in the light oils of wood naphtha. It was ascertained by its discoverer to boil between 128° and 130°. My experiments led me to fix its boiling boint a little lower, at 126·28; and as I obtained from coal naphtha an oil having the same composition and properties, and yielding apparently the same derivatives, I concluded the two hydrocarbons to be identical. Mr. Warren fails to discover in his sample of coal naphtha this hydrocarbon boiling at 126°—he concludes at once that it does not exist in any coal naphtha, and that my experiments are untrustworthy. As, however, Mr. Warren makes out Cahours to have been wrong as to his xylole, and tells us that Mansfield mistook cumole for cymole, I cannot think myself very badly off in sharing with those eminent chemists the censure of Mr. Warren, for, "if gold rust, what should iron do?" The liquid which Mr. Warren calls xylole is the petrole of Bussenius and Eisenstuck;[‡] the pseudocumole[§] of W. De la Rue and H. Müller; my paraxylole,[‖] and has also been redescribed by Béchamp[¶] and by Naquet.[**] But that the true xylole discovered by Cahours really does exist I cannot doubt. I would here merely add that the boiling point of my xylidine,[††] 213°—214°, differs by little more than 1° from the number assigned by Deumelandt[‡‡] to xylidine obtained from a coal naphtha fraction boiling 13° above that which yielded my product.

The case of cymole still remains. Warren does not find this hydrocarbon in coal naphtha, while he affirms the boiling point of the cymole from oil of cumin to be 179·6°. Dr. Noad, who prepared large quantities of this liquid, gives 171·5° as its boiling point, while my determination was 170·7° for the oil as distilled from sodium, and 175° to 176° after treatment with oil of vitriol. This number 175° is that now generally confirmed by other chemists as the true boiling point of cymole.

The discrepancies between some of my boiling points and those more recently determined depend in great measure upon the different corrections applied to the thermometric indications, and also upon the existence in coal naphthas of two series of isomers, which seem to me to have been jumbled together by some observers.

[††] *Phil. Mag.* 1855. [‡‡] *Zeitschrift für Chemie*, 1866, p. 21.

On this second point a word or two will at once explain my meaning.

Warren accepts 80·1° as the boiling point of benzole; the identity of benzole from various sources is generally allowed. Now cumole obtained from cuminic acid boils, according to Warren, at 151·1°. I do not suppose that any one has good grounds for controverting the statement that benzole from benzoic acid, and boiling at 80·1°, and cumole from cuminic acid, and boiling at 151·2°, are members of the same series. Both are derived by the same process from homologous acids.* If we compare, as we may fairly do, their boiling points, to what difference for C_3H_6 does it point? Not to Mr. Warren's 30°, but to the smaller difference of 23° or 24°.

		Difference for $3CH_2$.
Benzole	69·1°	71·1°—23·7° × 3.
Cumole...............	151·2°	

Nearly all the difficulties suggested by the divergent results of different experimenters will be explicable if the existence in various coal naphthas of two or more series of benzolic homologues be granted. Warren, while readily admitting the occurrence of several similar isomeric series in different kinds of natural and artificial paraffin oils, seems to deny the occurrence of analogous variations in different samples of coal naphtha.

II. The Parabenzole Series.—In treating of the boiling points of the benzole series, I have necessarily referred to the existence of an isomeric series of hydrocarbons. Warren makes the very obvious suggestion that parabenzole is a mere mixture of benzole and toluole. I originally entertained the same notion myself, till a close examination of the physical and chemical properties of this liquid convinced me that it was untenable. I have sufficiently combated this idea in my notes on the parabenzole series published in the volume of the Chemical News before cited.

The existence of an isomeric benzole has received strong confirmation in some experiments by Fittig, the occasional collaborateur of Beilstein. He finds a hydrocarbon, in some points closely resembling parabenzole, in the products of the distillation of camphor with zinc chloride.

I will add one fact about the occurrence of parabenzole in coal naphtha which may serve to account for its non-detection by some observers. My experiments were made with fractions boiling at about 100°, and which had been collected during some years in numerous distillations of large quantities of the naphtha; yet a few ounces only of parabenzole was the ultimate product.

III. Reactions, and New Compounds and Processes.—The following are the chief points under this head to which I would wish to call attention. I claim as my own the following processes, methods, &c., most of which have been republished of late years as new discoveries or adopted without acknowledgment:—

1. The purification of hydrocarbons by distillation from sodium. (*Phil. Mag.* 1855.)
2. The production of the so-called "nitro-sulpho" acids by dissolving nitrobenzole, &c., in oil of vitriol or Nordhausen acid. (*Ibid.* 1855.)
3. The oxidation, by chromic acid, of nitrotoluole and its homologues into β nitrobenzoic acid, etc. (*Ibid.* 1861.) In 1862 I showed in the International Exhibition a specimen of this β nitrobenzoic acid thus labelled and distinguished from the ordinary α acid.
4. The oxidation of sulpho-toluenylic acid into benzoic acid by the action of the chromic acid.
5. The probability of the existence of methyl-benzole, &c. (*Phil. Mag.* 1859.)*

I trust that none of the foregoing remarks will lead any one to suppose that I underrate Mr. Warren's own researches. While demurring to much of his criticism, I look upon some parts of his experimental investigation as monuments of patient labour and as most valuable additions to our accurate knowledge of a complex subject. And, with reference of Professor Beilstein, I am far from denying that in some particulars his criticism, though rough, is just. For example, in my earlier papers I rested my convictions of the identity of some of the benzolic homologues from various sources upon experimental grounds, which have since been shown to be inadequate. Then, again, I stated in 1855 (*loc. cit.*) that coal-tar toluole, by digestion with sodium, yields two hydrocarbons differing in boiling point—an asssertion which is erroneous if pure toluole be operated upon, but which I myself corrected in 1857, explaining, at the same time, the real facts of the case. In the other charges which Professor Beilstein brings against my statements, I believe him to be unjust, and that he is so in some instances may be proved very readily. He states† that I assert xylole to be changed into benzoic acid by oxidation with chromic acid. The fact is that, on the contrary, I offered no experiments of my own on the subject, but simply stated‡—"I have *not* yet experimented with the *xylole* series!" The last matter in which my reputation is assailed is as to the identity of the α and β nitrobenzoic (nitrobenzoic and nitrodracylic) acids; as already stated, I affirmed them to be different as early as 1862. But Professor Beilstein is not content with charging me with the terrible mistake of confounding two bodies which every one knows are actually *isomeric*, for he does me the further kindness of recommending *my* process as the best method of preparing the β nitrobenzoic acid! He does this without acknowledgment in his attack on another chemist.§.

On the Separation of Tin and Arsenic,
by Professor Wöhler.

This method is based upon the solubility of sulphide of arsenic in bisulphite of potash, which does not dissolve sulphide of tin. The mass, oxidised by nitric acid, is allowed to digest with sulphur and caustic potash till solution is complete (or till the formation of a metallic oxysulphide, which is separated by filtration). The liquid, treated by excess of sulphurous acid, is allowed to rest for some time, and is then evaporated till two-thirds of the water and all the sulphurous acid have gone off. Filter off the sulphide of tin, and wash it, not with water, which must not be used here, but with a concentrated solution of chloride of sodium. This may be removed from the precipitate by means of a slightly acid solution of acetate of ammonia, but the liquor so obtained must not be added to the washing waters charged with salt. The sulphide of tin, when dried, may be converted into oxide of tin by roasting in contact with air. The arsenic which the liquid contains in the state of arsenious acid may be precipitated by a current of sulphuretted hydrogen.

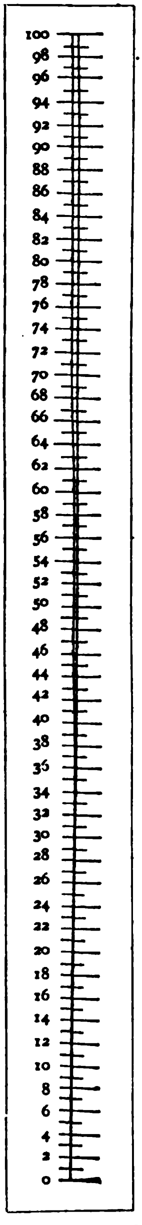
On the Application of the Blowpipe to the Quantitative Determination or Assay of certain Metals, by DAVID FORBES, *F.R.S., etc.**

Determination of the Weight of the Silver Globule obtained on Cupellation.—As the amount of lead which can, by the method before described, be conveniently cupelled before the blowpipe, is necessarily limited, the silver globule which remains upon the bone-ash surface of the cupel at the end of the operation is, when substances poor in silver have been examined, frequently so very minute that its weight could not be determined with correctness by the most delicate balances in general use.



The blowpipe balance employed by the author turns readily with one-thousandth of a grain, but could not be used for determining weights below that amount.

Globules of silver of far less weight than one-thousandth are distinctly visible to the naked eye—a circumstance which induced Harkort to invent a volumetrical scale based upon the measurement of the diameters of the globules, which scale in practice has been found of very great utility in the blowpipe assay of silver.

The scale for this purpose which is employed by the author is shown in full size in the annexed woodcut.

This figure represents a small strip of highly polished ivory about 6¼ inches long, ¾ inch broad, and ⅛ inch in thickness, on which are drawn, by an extremely fine point, two very fine and distinct lines emanating from the lower or zero point, and diverging upwards until, at the distance of exactly six English standard inches, they are precisely four-hundredth parts of an inch apart. This distance (six inches) is, as shown in woodcut, divided into 100 equal parts by cross lines numbered in accordance from zero upwards. It is now evident, if a small globule of silver be placed in the space between these two lines, using a magnifying glass to assist the eye in moving it up or down until the diameter of globule is exactly contained within the lines themselves, that we have at once a means of estimating the diameter of the globule itself, and therefrom are enabled to calculate its weight.

As the silver globules which cool upon the surface of the bone-ash cupel are not true spheres, but are considerably flattened on the lower surface, where they touch and rest upon the cupel, it follows that the weight of globules corresponding in diameter to the extent of divergence at the different degrees of the scale cannot be calculated directly from their diameters as spheres, but require to have their actual weight experimentally determined in the same manner as employed by Plattner.

The table here appended has been calculated by the author, and in one column shows the diameter in English inches corresponding to each number or degree of the scale itself, and in the two next columns the respective weights of the flattened spheres which correspond to each degree or diameter; for convenience these weights are given in the different columns in decimals, both of English grains and of French grammes.

These weights are calculated from the following data found as the average result of several very careful and closely approximating assays which showed that globules of silver exactly corresponding to No. 95 on this scale, or 0·038 inch in diameter, possessed a weight of 0·0475573 grains or 0·003079 grammes. From this the respective weights of all the other numbers or degrees on this scale were calculated, on the principle that solids were to one another in the ratio of the cubes of their diameters. This mode of calculation is not, however, absolutely correct in principle, for the amount of flattening of the under surface of the globule diminishes in reality with the decreasing volume of the globule. In actual practice, however, this difference may be assumed to be so small that it may be neglected without injury to the correctness of the results.

The smaller the diameter of the globule, the less will be the difference or variation in weight in descending the degrees of this scale, since the globules themselves vary in weight with the cubes of their diameters; for this reason, also, all such globules as come within the scope of the balance employed should be weighed in preference to being measured, and this scale should be regarded as more specially applicable to the smaller globules beyond the reach of the balance.

Chemical Composition of the Mud from the Streets of the City of London, by Dr. Letheby.*

During the last twelve months many analyses have been made in my laboratory of the mud from the City thoroughfares, with the view of ascertaining the relative proportions of horsedung to the matter from the abraded stones and iron of wheels and horseshoes; and the results show that the former material averages about 57 per cent. of the dried mud.

It was first ascertained that the amount of moisture in the street mud varies to a considerable extent, according to the state of the weather, but it is rarely less than 35·3 per cent. of the weight of the mud in the driest weather—the average of ordinary weather being 48·5 per cent.—and in wet weather it ranges from 70 to 90 per cent.

After all moisture has been driven off from the mud by exposing it for many hours to a temperature of from 266° to 300° of Fahrenheit, the relative proportions of organic and mineral matters were as follows; and for comparison the composition of well-dried fresh horsedung and common farmyard dung has also been determined:—

Composition of Mud from the Stone-paved Streets of the City, compared with fresh Horsedung and Farmyard Dung dried at 300° Fahr.

Constituents.	Fresh Horse-Dung.	Farm-yard Dung.	Mud from Stone paved Streets. Maximum Organic.	 Minimum Organic.	 Average.
Organic matter .	82·7	69·9	58·2	20·5	47·2
Mineral matter .	17·3	30·1	41·8	79·5	52·8
	100·0	100·0	100·0	100·0	100·0

The largest amount of mineral matter is always found in the mud in wet weather, when the abrasion of the stone and iron is greatest. At that time it may amount to 79 per cent. of the weight of the dry mud; whereas, in dry weather, it does not exceed 42 per cent. Taking the average of all weathers, the amount of horsedung to abraded matters is about 57 per cent.

The exact proportions of stony and ferruginous matters in the mineral constituents of the mud have not been determined; but from the deep red colour of the ash obtaining by incinerating the mud, there can be no doubt that the proportion of iron in the mud is very large; and it must have been derived from the wheels and horseshoes abraded by the stones.

In the case of the wood pavement, the amount of organic matter in the dried mud was larger than in the case of the stone pavement. It amounted, in fact, to about 60 per cent., and the ash was highly ferruginous.

Very probably the average proportions of horsedung, abraded stones, and abraded iron in the mud from the stone-paved thoroughfares is about as follows: —

Horsedung	57
Abraded stone	30
Abraded iron	13
	100

The mud was in every case so finely comminuted that it floated freely away in a stream of water, and the inference is that it would not subside to any great extent in a sewer with a moderate flow of water.

On the Invariableness between the Ratios of the Weights of the Elements forming Chemical Compounds, by J. S. Stas.

I have already stated that the laws of chemical proportions are not mathematically proved. Indeed, the attentive examination of all the facts in the science

---

* Communicated by the author.

bearing upon this subject has convinced me that chemists rely rather upon the constancy of the composition of compounds, than upon a rigorous demonstration of Wenzel's law, and of Dalton's hypothesis, known as the *law of multiple proportions.*

I shall not here examine Gay-Lussac's celebrated article "*On the Mutual Combinations of Gases*,"[*] nor Wollaston's article "*Upon the Carbonates and the Oxalates*,"[†] which, since the commencement of this century, have served as the experimental basis of Dalton's hypothesis. It is now allowable to affirm *a priori* that Gay-Lussac has not succeeded in proving his *law of volume* as a mathematical law; for, in fact, it can only be correct within certain limits, since the law of the compressibility of elastic fluids and the law of the expansion of gases by heat are themselves only approximately correct. The experiments of Wollaston on the relations of oxalic acid and potash in the neutral and acid oxalates were performed upon such a small scale that it is impossible to tell from them if the law of multiple proportions is a mathematical or an approximate law. Even admitting the quantities to have been sufficient, the principle relied on by the famous English chemist—viz., *neutrality measured by colouring matter*—is but an hypothesis whose basis requires *à priori* proof.

All the analyses and the syntheses yet performed are quite powerless to prove the law of definite proportions to be a mathematical law. For, whatever skill a chemist may possess, it is impossible for him to perform an analysis or synthesis without committing an error of observation. Now, hitherto, nothing has proved that the differences found in certain analyses between experiment and calculation must be *wholly* owing to error in the operation; a certain part may be due to the inexactitude of the law of definite proportions. Then, again, if the existing analyses and syntheses could give an exact solution of this problem, all chemists would agree as to the atomic weights of a large number of bodies, and Prout's hypothesis would be definitely decided. The diversity which has long existed as to certain atomic weights proves better than any reasoning that an absolute proof of the law of definite proportions is still wanting.

The constancy of the composition of stable compounds being admitted, what is required to resolve this problem? It must be proved that in binary and ternary bodies, for example, having each *two elements in common*, the common elements exist with *invariably the same ratios as to weight.* Thus in two bodies, AB and ABC, the ratios of the weights of A to B should be just the same in AB as in ABC.

It may be seen that the solution of this problem may be made independently of analysis, for to resolve the problem it is merely required to discover if the ternary bodies may be reduced to binary bodies without any fraction, however small, of either of the common elements becoming free; or, inversely, if the binary may be transformed into ternary substances without any fraction of one of the elements of the binary compound remaining unincluded in the ternary compound.

Among all the facts composing the science of chemistry, there is not one which entirely satisfies these conditions. The transformation of the chlorate and bromate of potassium into the chloride and bromide under the influence of heat is the nearest approach of any. Chemists who have closely studied this decomposition of the chlorate have observed traces of chlorine only in the disengaged oxygen. In the analysis that M. Marignac made of this salt, he attempted to measure these traces of chlorine.[*]

For my part I have tried every means for fixing the chlorine on red-hot silver.[†]

In the hope of finding in the transformation of chlorate and bromate of potassium into chloride and bromide a solution of the problem in question, I made new and lengthy trials, but they were all fruitless. I always found traces of chlorine or bromine, although I had taken every conceivable precaution to deprive the chlorate and bromate of the infinitesimal quantities of silica or of foreign metals which they retain with the most persistent tenacity. I was not more fortunate with the perchlorate of potassium; however slowly I decomposed it by heat, and whatever pains I took to purify it, the oxygen it gave off by the action of heat was always, towards the last, contaminated by traces of chlorine.

Having failed in these attempts, I directed my researches in another direction. It is well known that sulphurous anhydride transforms into iodide of silver the iodate of that metal suspended in water, at the same time that it becomes sulphuric acid. I have shown that, under the same influence, bromate becomes bromide, and chlorate chloride, of silver. The absolute insolubility of iodide, bromide, and chloride of silver in water acidulated with sulphuric acid, and the possibility of recognising in a liquid a ten-millionth part of silver, of iodine, of bromine, or of chlorine, are exceptionally favourable conditions for submitting the law of definite proportions to a decisive test. For this purpose I undertook the researches I am about to describe.

These experiments were very difficult of execution There were two obstacles I had to contend with; the first, which is readily foreseen, consists in the great difficulty of procuring salts of silver sufficiently pure to be submitted to so rigorous a test; the other, which was quite unforeseen, is due to the property possessed by sulphurous acid of changing under the influence of still obscure, or rather completely unknown, causes, and of having, in its changed condition, peculiarities opposed to those which it possessed before undergoing this change.

It is of course impossible for me to give here any idea of the difficulties I met with in the preparation of *pure iodate, bromate, and chlorate of silver*; they were naturally different for each of their salts. As the different steps which I took will prove very instructive to those who would care to repeat these researches, I will relate very fully the means to which I had recourse to obtain these salts, and to ascertain their degree of purity.

On the Microscopical Examination of Coal Ash or Dust from the Flue of a Furnace, by J. B. Dancer, *F.R.A.S.*[‡]

When coal is burnt in a furnace to which atmospheric air has free access, a portion is converted into gaseous and volatile matter; and the incombustible substance which remains is the ash. The amount of ash in coals from different localities is very variable; it is said to range from 1 to 35 per cent. The ash or dust which is

[‡] Read before the Manchester Literary and Philosophical Society.

the subject of this paper was collected from the flue of my steam boiler furnace, in which common engine coal is used as fuel. This coal leaves a considerable amount of incombustible matter. A specimen of the dust is now before you; it is of a reddish-brown colour, and free from soot or carbonaceous particles.* When this dust is examined under the microscope with a power of 40 or 50 diameters, it is found to consist of ferruginous matter and crystallised substances, some particles transparent, others white and red. It contains also a number of curious-looking objects, which vary considerably in size and colour; the majority of these bodies are spherical, and when separated from the irregularly shaped particles forming the bulk of the dust they become interesting objects for the microscope. I shall confine my remarks more especially to these globular bodies. Some of these are as perfect in form as the most carefully turned billiard balls, and have a brilliant polish. The various colours which these globules exhibit give additional interest to their examination. Some are transparant crystal spheres, others are opaque white, many are yellow and brown, and variegated like polished agates or carnelian of different shades. The most abundant of the highly polished balls are black; there are others which look like rusty cannon balls—some of these have an aperture in them like a bombshell, and many are perforated in all directions. To obtain these objects the dust should be washed in a bowl and all the lightest particles allowed to float away; the remainder consists of fragmentary crystalline and ferruginous substances; mixed with these are the polished balls described, which, under the microscope, by a brilliant reflected light, look like little gems. To separate the spherical bodies from the irregular ones, it is only necessary to sprinkle some of this material on an inclined glass plate, and by gentle vibration the balls roll down, and can thus be collected. Having satisfied ourselves with the examination under the microscope, it is natural that we should desire to know more about these novel objects. What is their elementary constitution? Why are they spherical? How do they get into the flue? I have not attempted a chemical analysis of these minute bodies, many of which are less than the 100th part of an inch in diameter. I can only therefore offer an opinion as to their probable constitution, judging from what is known of the chemical analysis of coal ash, and from the appearance they present under the microscope. Referring to the chemical analysis of coal ash, we find that it sometimes contains silica, magnesia, alumina, sesquioxide of iron, lime, soda, potash, sulphate of calcium, anhydrous sulphuric acid, anhydrous phosphoric acid, sulphur, and sometimes traces of copper and lead. The vegetable origin of coal is now generally admitted, and doubtless some of the substances I have just named have been taken up by the coal plants, whilst other portions may have collected in the locality where the coal was formed. As this is not immediately connected with our present inquiry, I proceed to speculate as to the constitution of these globular bodies. The transparent spheres I imagine to be silicates of soda or potash; the opaque white are most likely silicate of soda or potash combined with lime and alumina; the yellow and brown are silicates coloured by iron in different proportions. The black globes are not all alike in composition; some of these are silicates coloured by carbon, others are iron balls coated externally with a silicate. Many of these rusty cannon balls are probably ferrous oxide formed by the action of heat on the iron pyrites in the coal. There are also balls of black magnetic oxide; the perforated shells are probably ferrous sulphides. The globular form of these bodies suggests that they have been thrown off in scintillations, such as are seen during the combustion of iron in oxygen gas, and whilst in a fluid state they assume a spheroidal form. They are carried by the draught into the flue, and being of greater specific gravity than the carbonaceous matter forming the smoke, they fall before the current of air has reached the chimney. Some of the dust has been a considerable time in the flue, exposed to the intensely heated circulating flame; the reducing action of this would probably convert some of the oxide into metallic iron. Many of these balls have the appearance of reduced oxides. The flue dust contains a larger amount of ferruginous matter than can be accounted for by the analysis of coal ash. I think the surplus may be regarded as representing the wear and tear of the iron work about the furnace, such as fire bars, boiler plates, &c. The brick work and cement about the boiler and flues may also supply some of the silica, alumina, and iron for these balls, numbers of which are merely thin shells. The movements of these objects, caused by the approach of a magnet under the stage of the microscope, are somewhat amusing, and it is at times startling to see the crystalline objects, both spherical and irregular, exhibit magnetic attraction; probably they contain particles of iron imbedded in them; if they do not, may we not imagine that there is some magnetic compound in which the crystalline matter predominates? When we consider the accidental condition under which this matter has combined, it is just possible that some new molecular arrangement or combination of elements may have taken place. It is very probable that many of these polished balls are much more complex in their elementary constitution than I have stated. They are, in fact, a kind of glass, and many of them merely bulbs. Pelouze states that glass is probably an indefinite mixture of definite silicates. Glass, containing small quantities of ferrous oxides and sodic sulphates, when exposed to sunlight, becomes yellow, and possibly some of these balls may have changed in colour since they came from the flue. Hydrochloric and nitric acid exert very little action on the ferruginous globes; this may be due in some measure to the high temperature at which the oxides have been formed; in other cases they are no doubt protected by an external coating of some silicate. It would require much time and patience to collect a sufficient number of each kind of these minute objects for a chemical analysis; but the spectroscope might probably assist in revealing their constitution. When time permits I hope to resume the subject.

On the Supposed Nature of Air prior to the Discovery of Oxygen, by George Farrer Rodwell, *F.C.S.*

XVI. J. C. Sturm.— John Christopher Sturm,* although not very notable in the science of pneumatics as an original investigator, did much to propagate the discoveries of others, and to induce pneumatical research. He has been called "*le restaurateur des sciences physiques en Allemagne*," but we cannot admit this designation, both on account of the inaccuracy of the expression, and because it behoves us to remember that Otto von Guericke, Gaspar Schottus, and Atha-

---

* My attention was drawn to this subject by Mr. Johnson, of Wigan, in November, 1866.

* Born at Rippolstein in Bavaria in 1635, died at Altorf in Franconia in 1703.

nasius Kircher were among his contemporaries, and with him assisted in the introduction of a taste for physical science into Germany. In regard to the inaccuracy of the above expression, we may remark that the term "*restaurateur* des sciences physiques" is incapable of being applied to any individual of the period in which Sturm lived. A *restorer* is one who brings back, or induces the return of, that which existed at some former time, but the physical sciences had no pre-existence, and therefore could not be restored. We may speak of "the restoration of learning," and of the "Renaissance period of literature," because we know that among the Greeks and Romans a noble and polite literature had arisen at a long prior period, and had been sustained by some of the most sovereign intellects which the world has beheld. We may speak of Petrarch as the restorer of *belles-lettres*, and of Cosmo de' Medici and Marsilio Ficino as the restorers of a taste for the Platonic philosophy, because an elegant and refined erudition and a love for the Platonic philosophy had pre-existed, and had for a time been extinguished. But this was not the case with physical science; it had no Renaissance period. In the age of Sturm it was new born into the world; hence he cannot be called its *restaurateur* in Germany, but may rather be regarded as an indefatigable and assiduous nurse, who helped to rear the young child, and to give it a good start in life.

We have no wish to depreciate Sturm, but rather to show that he is not entitled to the extravagant praise which one of his biographers (who probably committed this error of judgment "quoniam dilexit multum") awards to him. We do not think that the services of Sturm have ever been sufficiently recognised by the world at large, although they were undoubtedly well recognised in his own country during his lifetime, and in the succeeding period. Apinus speaks of him as "hic μαθηματικοτατος et per omnem Europam longe celeberrimus naturalis scientiæ Doctor;"* while Brucker at a somewhat later period designates him as "vir longe doctissimus et tum veteris philosophiæ, tum recentioris callentissimus, quique experientiam naturali philosophiæ optimo consilio junxerat, ut ex ejus Collegio Curioso constat."†

The "Collegium Curiosum" alluded to in the last sentence was a scientific society founded by Sturm in 1672 on the plan of the Accademia del Cimento. It originally consisted of twenty members, and it continued to flourish long after the death of its founder. The early labours of the society were devoted to the repetition (and often modification) of the most notable experiments of the day, and to the discussion of the results. Two volumes of proceedings were published by Sturm, the first in 1676, and the second in 1685; in them we find a collection of the principal pneumatic experiments of the Florentine academicians, and of Pascal, Boyle, Hooke, Otto von Guericke, and Huygens. The volume, which appeared in 1676, is entitled, "*Collegium Experimentale sive Curiosum. In quo primaria hujus seculi inventa et experimenta physico-mathematica . . . . . per ultimum quadrimestre anni* 1672. *Viginti naturæ scrutatoribus*, &c." The "*Programma Invitatorium*" is dated June 3,1672; and Sturm therein urges that inasmuch as the age of disputatious philosophy had given way to that of experimental philosophy, and as, moreover, scientific societies had been founded in Florence, London, Paris, Rome, and Venice, it would seem to be desirable to found one in Germany, for the attainment of which end he requests the collaboration of the learned.

The dedication of the work (to Antonio Magliabecchio, Duke of Tuscany) is a good example of the turgid and florid Latinity which prevailed in the dedications both of that and of a much later period. Then follows a list of the members, and a preface by Sturm describing the object and aims of the society, and the first chapter commences with an account of the diving-bell "recens inventa,"* and described by George Sinclair† in his "*Ars Magna et Nova Gravitatis et Levitatis.*" Next follow chapters relating to the camera obscura, the Torricellian experiment, the gravity of air, the water barometer, the mechanical powers, the thermometer, the air-pump, the microscope, the telescope, &c. In the 1685 volume (which is a continuation of the above), Sturm describes a modified form of Boyle's air-pump, which he had invented; but although by its means a partial vacuum was rapidly obtained, a good vacuum was impossible, because a spring was employed to close the valve, which allowed air to pass from the receiver to the pump barrel; but when the air within the receiver was much rarefied, the force exercised by its expansion was incompetent to overcome the pressure of the spring, and the receiver ceased to be further exhausted.

Altogether these two volumes would seem to constitute a nearer approach to a text-book of the very sparse (but rapidly increasing) physics of the period, than any preceding work. In addition to the above Sturm was the author of a large number of works, chiefly mathematical and physical.

Sturm was Professor of Mathematics and Natural Philosophy in the University of Altorff‡ for thirty-four years, and in that capacity possessed, and exercised, considerable influence as a propagandist of the new philosophy. His own studies had been pursued in the Universities of Jena and Leyden, in the former of which the Aristotelian philosophy prevailed, and in the latter the philosophy of Descartes. He commenced his career as a rigid Aristotelian, and afterwards became a syncretist,§ and endeavoured to unite the philosophy of

† "Institutiones Historiæ Philosophicæ." Lipsiæ, 1756.

* The invention of the diving-bell, is however, wrongly attributed to Sinclair, for it is mentioned by Bacon in the "Novum Organum," and by the Italian mathematician Nicolas Tartaglia.

† At that time Professor of Natural Philosophy in the University of Glasgow.

‡ This must not be confounded with its homonyme, the capital of the Swiss canton of Uri, which is a town of greater size, and in the present day of greater importance. The Altorff alluded to above is in Franconia, a few miles distant from, and under the jurisdiction of, Nuremberg. It is mentioned as early as the year 912, and in 1823 contained 1800 inhabitants. The University was founded in 1579 according to Lloyd ("Dictionarium Historicum, Geographicum, et Poeticum," 1686) and Hoffmann ("Lexicon Universale," 1698); and in 1575, according to Seally ("Geographical Dictionary," 1787) and Worcester ("Geogr. Dict.," 1823; but we must accept the latter date, because Apinus ("Vitæ Proff. Phil., etc.") gives the life of a professor who is described as holding office in the University in 1575. Seally in 1787 writes as follows:—"The fine University structure consists of a building three stories high, and contains in it a valuable library, an anatomical theatre, and a chemical elaboratory. In the main body of it is an observatory. . . It now contains about 200 students." In 1809 it was incorporated with the University of Erlangen, and it thus happens that one of the earliest homes of experimental philosophy in Germany has ceased to be recognised or noticed.

§ From συγκρινω to conjoin, cement together, applied to those who endeavour to unite the opinions of diverse sects into one system, and thus to produce a comprehensive coalition system, and a consequent coalition of sects. Brucker has well observed—"Parum utilitatis attulisse philosophiæ hoc syncretismi studium, res ipsa et eventus loquitur. Frustra enim philosophiæ veræ auctoritas hominis aut sectæ præfigitur, quæ non, quis dixerit, vel quid dixerint philosophorum principes, quærit, nec curat, utrum eorum effata salvari queant, sed quid verum sit meditatione duce inquirit."

Aristotle with that of Descartes, so as to produce a system participating in the dominant qualities of each. In this, however, he failed, and he then abandoned syncretism, and became essentially and completely a Baconian philosopher. In his thirty-seventh year we find him asserting that for a right investigation of nature the philosophy of Aristotle is not to be followed, neither that of Descartes, but the principles of truth and reason founded upon experimental proof.

Sturm was one of the first professors in Europe—"physicam scientiam juxta cum mathematicis publice docere." What a mighty revolution had occurred in this century in regard to the tolerance of individuality of opinion and the dissemination of free philosophical thought! Here we have the Baconian philosophy introduced into the very heart of a centre of learning without opposition, and with a simultaneous and necessary subversion of the Aristotelian philosophy. How well this contrasts with the intolerance exhibited by the Universities of Pisa and Padua (always noted for their strong adherence to Aristotle)—an intolerance which drove from the former University its greatest ornament and glory, Galileo!

It is not in the capacity of a great discoverer in science that we have here spoken of Sturm; it is not because he exercised a markedly direct influence either upon pneumatics or pneumatic chemistry; but because, by indirect means, he did much for the furtherance of those branches of science; because he helped to induce a permanent and wide-spreading taste for physical science; finally, because he laboured long and lovingly, and in the true spirit of the Baconian philosophy.

The University which he adorned—"ubi mathesin et physicam summa cum laude et applausu docuit"—has passed away, and with it the memory of the man. It would seem to be forgotten that he established in the heart of Europe a centre for the propagation of experimental philosophy; it would seem to be forgotten how deeply he stamped his name upon the times in which he lived, and how great has been the after-influence:—the letters are all but obliterated, and it has become necessary to grave them more deeply before they quite disappear.

TECHNICAL CHEMISTRY.

*On the Manufacture of Caramel Brown,** *by* Thos. Sherlock.

Caramel brown may be prepared in a variety of ways from glucose, molasses, or cane sugar. The following process gives a uniform and perfectly satisfactory article, and after having manufactured large quantities of the colour and tried several other processes, I have come to the conclusion that this is the best.

Provide an iron pan capable of holding twenty imperial gallons. Provide also an iron paddle or stirrer, flattened out broad at the end, about four feet long, and made light enough to be handled easily. Have also close at hand three or four gallons of clean boiling water. Set the pan on a ring over a fireplace, and put in half a hundred weight (56 lbs.) of good ordinary raw sugar. It is mistaken economy to use the very commonest brown sugar. Light a fire under the pan, and as it burns up stir the sugar about with the paddle. The sugar gradually melts, giving out puffs of vapour, and finally becomes a viscid liquid of a light brown colour. This is the first stage in the process. Only a moderate heat is required, and the melting should not be hurried. Now increase the heat gradually, stirring briskly and constantly. The liquid will become thinner and darker in colour, and at length begin to boil vigorously and rise up in the pan. The whole secret consists in the management of this part of the process, and minute attention should be paid to the following simple directions. Allow the melted mass to rise up till the pan is half full; then open the fire-door, throw water on the fire, and pull it out quickly. This should be done by a second person, the actual operator stirring sharply with the paddle to keep the mass in the pan. If the fire be drawn without first throwing water on it, the contents of the pan will inevitably boil over, and there will be a corresponding loss of product. Continue the stirring till the boiling subsides, and the dark brown mass lies quiet at the bottom of the pan. If a little be now dropped on to a cold plate or piece of metal, it will solidify to a brittle lump, of a clear rich brown colour, showing that the operation has succeeded. All that now remains is to add sufficient water to bring the mass to the desired consistence. The water must be boiling when added, and in very small quantities at a time. There is a considerable rush of steam as the first portions of water are stirred in, and care must be taken in using the paddle to stand clear of the hot particles projected from the pan; but after a few additions of water all this subsides, and the water may be added more freely.

The finished colour is usually sent out, either as a stiff paste-like extract, in which condition it is used by saddlers, curriers, &c., for browning certain kinds of leather, or as a syrup more or less thick. In this last form it is used for colouring vinegar, spirits, gravies, and many other liquids, and is well known in the drug trade as "color fuscus." If the stiff form be required, about a gallon of water will be sufficient, and in this case the product should be got out while hot, and put into stone-ware jars, previously heated, and standing on a piece of wood.

Fifty-six pounds of raw sugar should yield at least 60 lbs. of the stiff colour, and proportionately more of the thinner kind, and when cold should dissolve readily in water, giving a clear brown solution, without deposit or turbidity.

The causes of failure in the manufacture may be either a deficiency or an excess of heat.

If the heat used be insufficient, some of the sugar remains imperfectly converted, and a muddy dirty-looking product is the result. On the other hand, if the heat used be excessive (strong heat is not required in any part of the process), the mass becomes black, granular, and insoluble in water—in fact, burnt and useless.

*Note on the Bituminous Schists of Vagnas (Ardèche).** *by* M. L. Simonin.

This bed of schist, now worked, merits notice. It is more a sort of tertiary boghead than a true schist. Its texture is compact and massive, like that of carbonised and compressed peat. Its origin from peat is further revealed by the numerous very delicate vegetable filaments apparent to the naked eye in the rock.

---

* Communicated by the author.

* Communicated by the author.

The schist, distilled in a revolving retort, gives about 10 per cent. by volume of raw paraffin oil. This oil is decarburetted in a fixed retort, and gives, with a lighter oil, a very pure coke as residue. The tar is separated from the decarburetted oil by means of sulphuric acid and soda, and it furnishes an oil that is purified by a second distillation and a new treatment with acid and alkali. The result is a white opalescent light oil, of a specific gravity of 0·825°, and an agreeable ethereal odour. The illuminating power is that of nine ordinary wax candles, and the point of combustion is 158° F., whereas the American oil inflames at 113° F.

The yield of light oil is 5 per cent. of distilled schist, and the secondary products are the coke above mentioned, the acid tars, paraffin, &c. The distilled schist serves as a combustible for all the operations of the manufactory; also, for the same purpose, the lignites, too poor to be distilled into mineral oil, are made use of.

PHYSICAL SCIENCE.

*On the Occlusion of Hydrogen Gas by Meteoric Iron,** *by* Thomas Graham, *F.R.S.*

Some light may possibly be thrown upon the history of such metals found in nature as are of a soft colloid description, particularly native iron, platinum, and gold, by an investigation of the gases which they hold occluded, such gases being borrowed from the atmosphere in which the metallic masses last found themselves in a state of ignition. The meteoric iron of Lenarto appeared to be well adapted for a trial. This well-known iron is free from any stony admixture, and is remarkably pure and malleable. It was found by Wehrle to be of specific gravity 7.79, and to consist of—

Iron	90·5883
Nickel	8·450
Cobalt	0·665
Copper	0·002

From a larger mass a strip of the Lenarto iron 50 millimetres by 13 and 10 millimetres, was cut by a clean chisel. It weighed 45·2 grammes, and had the bulk of 5.78 cubic centimetres. The strip was well washed by hot solution of potassa, and then repeatedly by hot distilled water, and dried. Such treatment of iron, it had been previously found, conduces in no way to the evolution of hydrogen gas when the metal is subsequently heated. The Lenarto iron was enclosed in a new porcelain tube, and the latter being attached to a Sprengel aspirator, a good vacuum was obtained in the cold. The tube, being placed in a trough combustion furnace, was heated to redness by ignited charcoal. Gas came off rather freely, namely—

In 35 minutes	5·38	cub. centims.
In 100 minutes	9·52	"
In 20 minutes	1·63	"
In 2 hours 35 minutes	16·53	"

The first portion of gas collected had a slight odour, but much less than that of the natural gases occluded from a fire by ordinary malleable iron. The gas burned like hydrogen. It did not contain a trace of carbonic acid, nor any hydrocarbon vapour absorbable by sulphuric acid. The second portion of gas collected, consisting of 9·52 cub. centims., gave by analysis—

Hydrogen	8·26	cub. centims.	85·68
Carbonic oxide	0·43	"	4·46
Nitrogen	0·95	"	98 6
	9·64		100·00

The Lenarto iron appears, therefore, to yield 2·85 times its volume of gas, of which 86 per cent. nearly is hydrogen. The proportion of carbonic oxide is so low as 4½ per cent.

The gas occluded by iron, from a carbonaceous fire, is very different, the prevailing gas then being carbonic oxide. For comparison a quantity of clean horseshoe nails was submitted to a similar distillation. The gas collected from 23·5 grammes of metal (3·01 cub. centims.) was—

In 150 minutes	5·40	cub. centims.
In 120 minutes	2·58	"
In 4 hours 30 minutes	7·98	"

The metal has given 2·66 times its volume of gas. The first portion collected appeared to contain of hydrogen 35 per cent., of carbonic oxide 50·3, of carbonic acid 7·7, and of nitrogen 7 per cent. The latter portion collected gave more carbonic oxide (58 per cent.) with less hydrogen (21 per cent.), no carbonic acid, the remainder nitrogen. The predominance of carbonic oxide in its occluded gases appears to attest the telluric origin of iron.

Hydrogen has been recognised in the spectrum analysis of the light of the fixed stars, by Messrs. Huggins and Miller. The same gas constitutes, according to the wide researches of Father Secchi, the principal element of a numerous class of stars, of which α Lyræ is the type. The iron of Lenarto has no doubt come from such an atmosphere, in which hydrogen greatly prevailed. This meteorite may be looked upon as holding imprisoned within it, and bearing to us, hydrogen of the stars.

It has been found difficult, on trial, to impregnate malleable iron with more than an equal volume of hydrogen, under the pressure of our atmosphere. Now, the meteoric iron gave up about three times that amount, without being fully exhausted. The inference is that the meteorite has been extruded from a dense atmosphere of hydrogen gas, for which we must look beyond the light cometary matter floating about within the limits of the solar system.

FOREIGN SCIENCE.

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Group V.—Class 44: Chemical and Pharmaceutical Products.

Felix Dehaynin, of Paris, has founded at Aubervilliers, near Paris, some large chemical works, for the treatment, on a large scale, of the products of the distillation of coal tar. One would scarcely believe that the quantity of coal tar annually distilled in the manufactory of Gosselies, where the dust and small coal are agglomerated in the form of small bricks, of immense utility for railway locomotives, amounts to eight or ten thousand tons. It is then treated by another operation, and transformed into benzol, nitrobenzol, and aniline, substances emlyoyed for the preparation of the new colours, the solution of caoutchouc, removal of grease from stuffs, leather varnishing, etc. The benzol,

---

* Read before the Royal Society, May 16, 1867.

nitrobenzol, and the aniline of Aubervilliers are much esteemed. The eye cannot contemplate without astonishment the array of twenty-five bottles, which only form a part of the products of the distillation of coal.

The glass case of M. Robinet, of Paris, 3, Rue de l'Abbaye Saint-Germain, formerly President of the Academy of Medicine, is distinguished from his neighbours' by the fact that he sells nothing, that he gives away all the products he obtains—that is to say, his numerous analyses of waters —and he limits himself to the task of soliciting new ones, which he analyses in succession, and gives gratuitously the results of his analyses to those who send the samples. He even goes so far as to give bottles of certain waters to those who, for particular reasons, would be interested in knowing the nature of those in their neighbourhood; and he bears the expense of carriage, bottles, &c., even if they are sent to the other end of the world. What motive has induced M. Robinet to make so many great sacrifices, and to give himself so much labour? Nothing is more simple to answer. He has undertaken to fill up a void in the physical history of our country; he has given to science, industry, agriculture, and public salubrity, a Hydrographic Dictionary of France. There exist, undoubtedly, already, numerous documents from which such a work might be compiled; but they are scattered about and incomplete. The "Geographical Dictionary" no longer exists. The work of 221 pages, published under this title in 1787, by M. Mothey, geographer to the king, did not fulfil the required result. M. Robinet set courageously to this task after the work he had performed as reporter to the commission of inquiry for the diversion of the waters of the Dhuys. He proposes to treat of soft or potable waters in a statistical, geographical, geological, chemical, economical, hygienic, and agricultural point of view. A first essay, already published, devoted to the study of the basin of the Marne, amply proves that the author will complete his programme.

In his glass case we find a hundred specimens of water, and one of the labels bears the number 2082. In fact, M. Robinet has analysed more than 2000 waters! His exhibition is only intended to invite remittances of water from the four quarters of the globe. We would say that his appeal has already been responded to, for we find in the galleries waters from London, the Danube, &c., and there is every reason to hope that the geographical dictionary especially devoted to France will also interest, in a greater or less degree, most of the foreign nations. We sincerely wish that, among the numerous pilgrims to this great *fête* of nations, some will not object to encourage his work and send specimens of waters. The notation for the representation of watercourses of M. Robinet is well worthy the attention of hydrographic and other engineers, his new system gives immediately a very exact idea of the direction, extent, inclination, and other essential characters of watercourses. In order that the remittance of water to be examined may be complete, it should comprise the waters of the rivers, brooks, and wells, with the nature of the soil in which they rise, drainage water, rain water collected in an earthenware or porcelain vessel, and drinking water from the public fountains.

We find in the glass case of M. Joly, of La Rochelle and Paris, No. 13, Rue d'Antin, a very original and new product —viz., marine silk. M. Joly discovered in the eggs of fishes of the family of Sebacians (the ray) that their exterior envelope is formed of a very close tissue, composed of an infinite number of delicate filaments which are easily removed and separated. Once drawn out they possess the appearance, colour, and finish of cocoon silk, serving without trouble for tissues of ordinary silk or silk wad. The interior of the eggs contains an albuminous white substance which can serve usefully in competition with the white of hens' eggs for printing on tissues; they contain a considerable quantity, as each roe weighs on an average 240 grammes (about ½ lb) The manufacturing industry of tissues will certainly make good use of these new products.

We also remark in the collection of M. Joly:—1. His cream of cod-liver oil, much more agreeable to the taste, and more digestible, than the best and purest ordinary cod-liver oil. 2. His Squalus-liver oil, which M. Joly was the first to think of extracting from these fishes. 3. Fish-liver oil for leather manufacture. 4. French guano, a manure formed of inedible fish and the debris of fisheries, very much sought after by agriculturists, and which is likely to improve the condition of the fishermen, as they can sell with profit what was formerly thrown into the sea.

The pharmaceutical establishment of M. Ch. Genevoix, 48, Rue Bonaparte, was the first that, thirty years ago, manufactured in quantities of a ton a day, ferruginous pills and lozenges. His syrups of iodide of iron and his purgative lemonade are remarkable for their indefinite preservation. His gaseous powder replaces, weight for weight, and with much economy, tartaric acid in the preparation of aerated waters in the gazogene apparatus with two compartments. The Paris hospitals employ every year, on an average, 10,000 packets. The quality, the attractive form, the low price, and excellence of manufacture combine to render the establishment of M. Ch. Genevoix a model pharmacy.

M. Emile Genevoix, 14, Rue des Beaux Arts, exhibits feculous seeds and fruits containing from 1 to 10 per cent. of different oils which play an important part in alimentation. Disseminated between the grains of starch, these oils can be extracted by means of sulphuret of carbon, chloroform, benzol, ether, &c. M. Genevoix substituted for these solvents, firstly, carbonisation by sulphuric acid, which, in spite of the high temperature produced, set the fatty matters at liberty, without destroying them, in a state easily soluble in menstrua, or able to be obtained in a greater quantity by distillation. But this method was too costly when it was used on the large scale, and it has given place in the factory of M. Genevoix to an industrial process which allows the production by tons weight of the oil of some fruits, very abundant and without value—the horse-chestnut, for example. Bought at 40 or 50 fr. the ton, the finest chestnuts are rasped, submitted to a full fermentation, boiled in ten times their weight of water, and transformed into glucose by the addition of 2 per cent. of sulphuric acid. The liquor, freed from insoluble portions, is submitted to a slow ebullition, which allows the oil to agglomerate at the surface particle by particle. Drawn off and filtered, this oil is sold to the public without any addition. For ten years past the average quantity of oil manufactured in the chemical works at Romainville has been 600 kilogrammes, extracted from fifty or sixty tons of horse-chestnuts which were bought from agriculturists for 2500 to 3000 fr. The wholesale price of the oil is 20 fr. Vegetable wax is separated from it under the form of stearin, margarin, &c. The water on which the oil floats, when neutralised, gives "syrup of glucose," and "horse-chestnut alcohol," prepared for trade on a large scale. The fabrication of starch had to be abandoned, as the supply of horse-chestnuts was uncertain and insufficient.

This fatty substance, very fluid, absorbable by the skin, has a place marked out in the therapeutics of the gout and rheumatism—in fact, the chestnut oil of M. Genevoix has been found very efficacious, and enjoys a great success.

M. Genevoix, struck with the happy effects obtained by the valerianate of ammonia, has combined valerianic acid with other new base. His valerianate of triamyline contains four equivalents of valerianic acid. If the medicinal action depends upon the acid, and not upon the base, the new compound cannot fail to be successful.

Poultices are attended with great inconvenience in consequence of their weight, their cooling, and their more or less disagreeable odour. For the application on the skin of liquid medicaments, laudanum, tincture of iodine, or fatty matters, M. Genevoix proposes an impermeable tissue enclosing a double layer of swanskin, which is wetted with a decoction of marshmallows, linseed, or poppyheads, and which preserves its temperature for more than twelve hours at 70° C.

M. Boboeuf, No. 9, Rue Buffault, Paris, the inventor of sodiac phenol, is an old acquaintance of ours. We have often enough spoken of him to permit us to say only a few words to-day. Along with phenol he exhibits magnificent specimens of phenic acid and picric acid manufactured by his processes. Thanks to him, the price of phenic acid has descended from 100 to 5 fr. the kilogramme; that of picric acid from 60 to 14 fr. His perfumed phenol, of which the odour is really agreeable, and the hygienic and preservative qualities are incontestable, will vie with the most popular toilet water and dentifrices. His phenol soap will certainly be useful in the therapeutics of skin diseases. It suffices to comb the head a few times with a comb dipped in a small quantity of phenate of soda, to cause all pimples, greasy or dry scurf, &c., to disappear. He obtained the Monthyon Prize, and a most favourable report was made by M. Kuhlmann in September, 1866, at the Mulhouse Industrial Society. These honours, joined to his commercial success, recommend M. Boboeuf to the attention of the jury.

M. Scipion-Dumoulin, No. 5, Rue St. Claude, commenced, in 1820, by the preparation of unalterable ink, rendering forgery impossible. This ink was favourably reported upon at the Academy, by Vauquelin and Deyeux. In 1842 he took out a patent for employing essential oils in a lamp, called the *gazomètre*, which was put into activity or stopped by means of a cock; it was a prelude to the Mille gazo-lamp, which was not possible in those days, as the lighter oils did not exist. In 1852 he devised a carburator, a vase or reservoir containing a spongy matter soaked in volatile essence for extra-carburising the gas passing through it. The means of procuring the gas without machinery is a secret discovered by M. Mille, by which the air or gas is charged spontaneously by passing over the volatile matters so as to be rendered more inflammable. In 1851 he communicated to the Academy of Sciences a new process for preparing picric acid by the reaction of nitric acid on the quasi-resin of canauba palms. This forms picric acid, and another part of the resin is transformed into wax like beeswax. The process is carried on with success in several manufactories of Lyons; the picric acid obtained is very pure, and is not greasy like the acid extracted from coal tar; it is very detonating, and explodes at the least shock. M. Payen repeats every year this experiment in his course of lectures.

In 1862 M. Dumoulin proposed to replace the oxide of lead glaze used for culinary purposes, at the potteries, by a glaze completely unalterable by alkalies and acids. Aided by a skilful potter, he thought at first he had realized the wished-for improvement, but it was otherwise; after a short struggle he gained the ground. He exhibited first in 1855 his liquid glue first discovered in 1850, which Francis Arago presented to the Academy on September 27, 1852, as solving a very difficult problem. The process was given voluntarily to the world by M. Dumoulin—it consists in pouring a small quantity of nitric acid into a solution of common glue or gelatin in its own weight of water. This glue, of two sorts, brown and white, is very strong, and is employed in private houses, workshops, and by jewellers, clockmakers, &c. Thousands of phials are sold abroad. To this liquid M. Dumoulin has added a cement insoluble in boiling water, and which rendered great service in the restorations at the Campana Museum. We may mention his cobalt green and blue, which were the first in France which really opposed the blues and greens of Saxony; his process of gilding and silvering without the battery, very easily and promptly effected by means of precipitated gold and silver, which render so much service in the jewellery art; his new ink, double black, prepared since 1853, without salts of iron, and incapable, therefore, of corroding the pens or paper, possessing from the first moment, and preserving indefinitely, its deep colour.

In 1860 M. Jean-Henri Chaudet, of Rouen, was the first to propose the use of bisulphite of soda or *leucogene* for wool bleaching, which is now universally employed in France, Belgium, Italy, Prussia, and Russia. In a tub filled with cold water, the first operation is to pour 18 litres of leucogene at 25° for every 100 kilogrammes of wool to be bleached. The wool, washed and scoured as well as possible, is steeped for at least three hours in this bath, and left to drain over the tub so as to save all the liquid. It is then dried in the open air. The same bath serves for any length of time, provided at each operation there are added nine fresh litres of leucogene per 100 kilogrammes of wool, with a sufficient quantity of water necessary to replace that used up by the preceding operation. The wools thus bleached have a whiteness which is permanent and more lasting than the bleaching obtained by sulphurous acid They can enter into the manufacture of tissues and other goods without the slightest danger of injuring the most delicate colours. Leucogene is an excellent decolorising matter if used in the bleaching of vegetable textile matters, such as cotton, linen, hemp, jute, or phormium. It gives a silky white colour to threads and tissues, that cannot be obtained with the hypochlorites. M. Chaudet manufactures annually 140 tons of leucogene, representing 2000 tons of white wool.

In 1866 he conceived the idea of applying bisulphite of soda and indigo to the blueing of wools. He has rendered great service to manufacturing arts by introducing an agent for permanently dyeing white wools blue by sulphurous acid. The process is extremely simple. All that is necessary is to add to the ordinary leucogene bath from three to five parts by weight of blue dye for every 100 kilogrammes of wool to be bleached. The operations of dyeing and bleaching take place simultaneously.

In the course of 1865–66, M. Chaudet effected another improvement in the industrial arts. Up to that time chromium was only employed as a mordant in the state of chromate, in which it acted the part of an acid. The colouring matter was often burnt by the oxygen of this acid, and the tints obtained changed rapidly when exposed to the air. By substituting for the chromate other salts in which chromium acted as base, new and permanent effects have been obtained. The salts used by M. Chaudet are the sulphate, the nitrate, and the oxalate of chromium. They are employed in the same manner as the salts of alumina. In copper vessels 4 or 5 by weight of sulphate of chromium, at 62° Beaumé, are dissolved as mordant for 100 of wool. The liquid is raised to a boiling point and left to simmer for two hours. The stuff is then washed and rinsed as usual. For vegetable substances such as flax, cotton, or hemp, the bath is composed of a solution of nitrate or oxalate of chromium, marking 1½° to 3° Beaumé. It is stove-dried, rinsed, and dyed. For printing, the ordinary method of operation is not changed, except that the acetate of alumina is replaced by the nitrate or oxalate of chromium, or the sulphate of alumina by the sulphate of chromium. With the salts of chromium as mordants, new shades of colour are obtained of a solidity before unknown.

(From our own Correspondent.)

Paris, May 28, 1867.

At the meeting of the Society of Encouragement on May 17, M. Tresca, who replaces M. Combe in the secretary's chair, paid a high compliment to the new steam engines of M. Duvergier, the constructor of the boats now plying on the Saone and Loire; he pointed out improvements in the machinery and in the employment of steam.

M. Julien Caudron, ropemaker at Malaunay (Seine Inférieure), submitted to the Society (Rope Section) ropes, splices, and knots of cotton, which, owing to their tested strength and cheapness, are preferred, for naval purposes, in some cases to hemp ropes. Experiments made at the several seaports amply confirm the hopes of the inventor.

M. Payen resumed, in a rather long but learned and interesting discourse, the progress accomplished in the fabrication of paper, parchment, and the employment of parchment paper for the separation, by endosmose, of the salts which hinder the extraction and crystallisation of sugar contained in juices, syrups, and molasses. After having called to mind the physical and chemical composition of herbaceous or woody fibres, he enumerated—1. The papers of MM. Bachet and Marehad, who treat the sprigs of fir first by hydrochloric acid, and afterwards by chloride of lime to bleach them. 2. The papers made from seaweed and other marine plants obtained nearly in the same manner by MM. Poinsot, Breton, &c. 3. The lucern papers of M. Caminade, the wild-thistle papers, the straw and sparta papers, &c. 4. Chinese rice papers, or those made from the pith of *Laruca poperia*; 5. The parchment papers of M. Neumann, at St. Denis. We shall not return to the subject of the osmose of sugars, as we think our readers are already sufficiently initiated into it.

M. Isambart had at work two magnesium lamps, the first being exactly similar to that of M. Solomon. A movement by clockwork rapidly unrolls the magnesium wire, which is coiled on a bobbin. It has the inconvenience of disengaging too much white vapours of magnesia, which for a moment obscure the light. The second is only a modified Larkin's lamp; and M. Isambart should not have omitted to mention his name. An ordinary spirit-lamp occupies the bottom; a glass tube forms a chimney; a small box or recipient containing magnesium in powder mixed with 50 or 80 per cent. of fine sand. By turning a small button a cock is opened; the mixture is inflamed, and burns with a very brilliant light. We prefer the first light to the second, of which the intermittent and unsteady light is intolerable to the eye. M. Isambart said that the expense per hour of the second lamp was about 3 fr., and that the price of magnesium may still be lowered. At 3 fr. this intense light is not too dear.

M. Durand presented, and set at work, a small model of a brick-making machine, representing one of the novelties of the Exhibition, of which we shall speak shortly.

M. Julien presented a pamphlet on iron and steel. We do not wish to enter into controversy here on this subject, only we notice that iron and carbon do not combine; they only mix together as water and oil.

M. Emile Petit sent specimens of artificial lithographic stones. We wish him success, as the lithographic presses of MM. Kocher and Houstiaux require for continuous impression cylindrical stones of a size difficult to be found in nature.

M. Lavollée, in the name of the Committee of Commerce, read a report on the exportation of the habitable constructions by M. Benis. Two portable private houses were sent out to the Island of St. Thomas. The walls were formed of two vertical and parallel sheets of scagliola or imitation of marble, the interior being filled up with wood shavings, alga marina, &c. The ceilings are partly of iron and partly of wood subjected to the process of injection of sulphate of copper and tar afterwards. The floors are of imitation marble, &c. The cost of the two houses was 45,000 fr., including 1100 fr. for the carriage. Their aspect is exactly that of houses built of marble.

M. Tresca made a communication on the mechanical applications in the interior of mines. Works in mines require a motive power, either sudden and discontinued or continuous and slow. In the first case, the best motor is, compressed air; in the second, water under pressure. As in tunnel work there can be no admission of fire, combustion, or the engendering of steam. Compressed air has been happily employed by M. Sommelier for the engines used by him in the tunnel of the Alps. Water under pressure was employed by M. Perret in the works of the South of France railways, to give a rotatory movement to the rings of circles of M. Deschaux, armed with diamond points for cutting the hardest rocks. The great problem of the day is the mechanical getting of coal. He explained and put before the eyes of the members two models; one of Carrett, Marshall, and Co.'s coal-cutting machine, the other of that of Jones, Levick, and Co., of Newport, Mon.

M. Chalmel, of Paris, exhibits a preservative varnish, used by all the great silversmiths and goldsmiths of Paris. This varnish is also very serviceable for copperplate engraving. He also exhibits an excellent green for water-colour drawings, miniatures, &c.; and oil of turpentine and lavender for the vitrification and incorporation of colouring matters on marble, porcelain, crystal glass, &c.

M. Bourgeois-Rocques, of Ivry (Seine), has adopted a singular method of manufacturing essences of wine. He sells it in small phials to vendors of natural and artificial liquids for the purpose of giving the colour, aroma, and "bouquet" of first-class wine crops, and of the best growers. For example he gives to the most ordinary white wines the perfume and taste of Sauterne.

The widow Madame Audouin, of Paris, exhibits a species of marine glue, which is susceptible of being put to an immense variety of uses. The forms are very variable—black glue, resisting the action of salt water; red, replacing minium; yellow, for staining wood; and soldering glue for sticking together wood, metals, glass, or porcelain.

CHEMICAL AND PHARMACEUTICAL PRODUCTS IN THE BRITISH SECTION.

(FROM ANOTHER CORRESPONDENT.)

In giving a short account of the chemical and pharmaceutical products of British manufacture in the French Exhibition, our object will, in the first place, be to state what the substances exhibited are, and in the next, whenever possible, to glance rapidly at the chemical reactions and principles involved in their production.

We need scarcely say that in a vast number of instances the Exhibition has simply been used as a means of advertising goods of no scientific merit whatever. In an almost equal number of cases the goods shown are devoid not only of all claim to the interest of scientific men, but are not even remarkable as representing any advancement in either manufacturing skill or inventive resource. In addition to these there are many instances where there are no means whatever of forming a judgment as to the quality of the substances exhibited. We allude to compounds and mixtures in liquid or powder, the true composition of which is a secret known only to the manufacturer. The chemical and pharmaceutical products form Class 44 of the Exhibition Catalogue; they are contained in Gallery V. of the building, and have been thus classified:—

Acids, alkalies, salts of all kinds, sea-salt, and products extracted from mother waters.

Various products of chemistry; wax and fatty substances, soaps and candles, raw materials used in perfumery; resin, tar, and the products derived therefrom; essences and varnishes; various coating substances, blacking, india-rubber and gutta percha and their products; dyes and colours.

Mineral and sparkling waters, natural or artificial.

Raw materials used in pharmacy, simple and compound drugs.

We shall take them as nearly as possible in the order in which they occur in the Catalogue.

The first exhibitors whose case we shall notice are the well-known firm of Allen and Hanburys, of Plough Court, London. They exhibit only two articles—viz., cod-liver oil and Liebig's extract of meat. Of the first of these two, there are samples manufactured in London and in Norway, both with the stearine, and also with so much removed as will crystallise out at ordinary temperatures.

Messrs. Allen and Hanburys inform us that they commenced the manufacture of cod-liver oil as early as the year 1843, and according to the directions then recently published by Professor Donovan. They have continued the manufacture regularly since that date, both in London and abroad, with only slight modifications of the original process. The oil is of a pale straw colour, and, when first made, has a sea-weed like odour, which, however, cannot long be preserved, no matter how carefully it has been prepared. Donovan's process, according to Cooley, is as follows:—"The perfectly fresh livers are placed in a metallic vessel and heated with constant stirring to 180°F., by which treatment they break down into a uniform pulpy liquid mass. This mass is immediately transferred to calico bags, whence the oil drains out; after filtration, while still warm, this oil is sufficiently pure for use."

Cod-liver oil is now so much used in medicine, that it has become a highly important article of commerce.

In this country we are inclined to look with more or less of suspicion upon any name that is connected with a largely advertised medicine. It is impossible to deny that the lustre of one of the most brilliant names in chemical science has been somewhat dimmed, at least in the eyes of the world, by being continually seen attached to jars of a highly nutritive but certainly uninviting-looking preparation in great favour at the present moment with the debilitated and dyspeptic.

This circumstance, although certainly unfair, is absolutely inevitable. There are few, therefore, who read the advertisements of "Dr. De Jongh's light brown cod-liver oil," who are aware that that gentleman (who, from the pertinacious way in which he has been decorated, appears to be a favourite with kingly amateurs of cod-liver oil) published in 1843 a most laborious research on the substance alluded to.

That cod liver oil is a valuable remedial agent in numerous diseases of a scrofulous type is now so generally conceded, that it would be a waste of time to argue the point. To which of the numerous ingredients detected by De Jongh we ought to attribute the active properties of the oil, is another matter. We need hardly say that the wildest views are entertained on the subject, especially by medical men, whose chemistry, as a general rule, is disgracefully defective. The subject is so important that we shall make no apology for quoting the analyses of the authority we have named. It is true that they show weak points, especially as regards the bile ingredients; the defects, however, are more easy to point out than to remedy, and, at the time the analyses were made, were not so obvious.

It is not remarkable that so many persons should entertain unsound views regarding the causes of the efficacy of cod-liver oil. Dr. De Jongh considers the value of the oil to be derived from the iodine and the elements of the bile. Others have imagined its curative properties to reside in the bromine, others in the phosphorus. It appears to us that these views are sufficiently refuted by the fact that none of the attempts to administer the ingredients of the oil in a separate state have succeeded. It is true that it has been attempted to evade this difficulty by saying that in cod-liver oil the substances alluded to are in a peculiar condition in which they are especially prone to assimilation. There is not the slightest evidence that this is the case. The free phosphorus has had the credit of being the really valuable ingredient. But is it absolutely certain that the phosphorus in cod-liver oil is free? Unless we are mistaken, the evidence for the existence of free phosphorus rests upon the fact that more phosphoric acid is obtained after oxidation of the oil with nitric acid than is obtained by precipitation from the liquid separated from the fatty acids after saponification. We think the evidence for the existence of free phosphorus requires to be greater than this. But, even assuming the fact, we think it in the highest degree doubtful if cod-liver oil, even if of the most absolutely correct "light brown" tint, possesses any remedial virtues save what are due to the fact of its being a highly digestible fat oil; and we consequently contend that the coloured and fœtid oils possess no curative properties that are not found in the carefully prepared and consequently nearly colourless oils—nay, more, that the disgusting flavour of the foul fish-oil of commerce, by rendering it more loathsome, in the same ratio renders it more difficult to assimilate.

(From our own Correspondent.)

Paris, June 18, 1867.

The Society of Mechanical Engineers of England held its annual meeting in Paris a few days ago, presided over by Mr. Penn, the celebrated constructor of marine engines. The meetings took place in the amphitheatre of the Conservatoire des Arts et Métiers, and many papers were read and communications made by the members. Amongst others were—"*Puddling by Machinery*," by M. Menelaus; "*Ventilation of Buildings*," by General Morrin; "*The Flowing of Solid Bodies through Orifices*," by M. Tresca, etc. Without presenting any novelty, the subjects brought forward were listened to with much interest. The scientific congress terminated with a magnificent banquet, at which 200 persons sat down. The meeting took place in the magnificent saloon of the Restaurant des Frères Provinciaux. Among the French celebrities invited we may mention General A. Morrin, M. Leverrier, M. Combe, M. Solacroup, director of the Orleans railways, M. Tresca, &c. Mr. Penn proposed, in the handsomest terms, the health of General Morrin, Messrs. Tresca, Fairbairn, and Stewart, of Mancester, and dwelt on the cordiality existing between the mechanical engineers of France and England.

M. Pasteur continues actively his researches on silkworms. He is now able to state that—1. Not a single silkworm, chrysalis, or moth derived from the eggs exempt from corpuscles presented any of these microscopic organisms; out of 16 sets of eggs laid, not infected with corpuscles, 15 succeeded. 2. The silkworms, chrysalides, and moths from the eggs obtained from corpusculous moths gave, in a more or less degree, the worms, chrysalides, or moths affected with corpuscles. M. Pasteur has also discovered in his researches another terrible malady, which he carefully describes, and for which the only remedy seems to be the renewing of the air by a shaft. M. Le Ricque de Monchy has found from his observations that creasote preserves healthy silkworms from parasitic diseases, and cures sick ones.

In submitting to the action of the poles of an electromagnet, bubbles of the glycerine liquid of M. Pasteur, filled with oxygen, M. Chantard, of Nancy, has succeeded in obtaining energetic attractions, and considerable oscillatory movements. He produces a sort of magnetic pendulum, which can be rendered visible to all by a ray of Drummond light.

The lectures at the great hall in the park of the Champ de

Mars commenced last week. They will be continued daily—at midday, 2 p. m., 4 p. m., and 8 p. m.—on different subjects, at the same time exhibiting and explaining various objects in the palace. For this purpose special authority has been granted by the Imperial Commission for the temporary removal of objects from the stalls to the lecture hall in the park. Excursions will also be made, accompanied by the audience, to visit and explain important objects in the main building, park, and reserved garden. The lectures at noon embrace subjects only indirectly connected with the Exhibition, such as lectures on the universal language of music, invented by M. Sudre; studies of India, by M. Giguel, etc. From 2 to 5.30 p m. the attention of the audience will be directed to various objects, and at 4 p. m. the subject is confined to those in direct relation with the Exhibition. Among the scientific lectures will be one by Dr. Crace Calvert on phenic acid and other analogous products. The new building is situated at the right of the Pont de Jena, next to the International Club building on the banks of the Seine. It holds 500 persons, and the decorations are carried out in the style and with the well-known taste of Parisian ornamentation. The electric light, the Carlevaris, Drummond, oxyhydro lamp (magnesia), and the millegazo lamp will alternately light up the interior of the hall.

F. MOIGNO.

(FROM OUR SPECIAL CORRESPONDENT.)

THE Glass Company of St. Gobain, Chauny, and Cirez, have four plate glassworks and two manufactures of chemical products.

The factories at Saint Gobain and Chauny are the oldest of those belonging to the Company. Their creation dates as far back as 1693. They comprise all the workshops, furnaces, and apparatus necessary for the manufacture of mirror and plate glass, thin white or coloured glass for dwellings, and thick slabs for lighting cellars. They also furnish moulded glass of a special quality for lenticular lighthouses, the cutting and polishing of which is executed in the workshops of MM. Henri Lepaute, Sautter, Barbier, and Fenestre.

The great lenses, which serve for enlarging photographic views in the apparatus of Worthly and others, are made at St. Gobain, as was also the great piece of glass 3 ft 11¼ in. in diameter for the great silvered mirror of M. Leon Foucault's telescope.

The glass plates, etc., cast at St. Gobain are sent to Chauny, nine miles off, to be polished, silvered, etc. At these immense works the motive power for grinding and polishing is 600 horse-power, partly furnished by a fall of water, and partly by steam. The polishing powders, such as emery, English red, etc., are there prepared. The manufacture of tinfoil for silvering glass is also carried on at Chauny, whence are supplied all the mirror factories of the Company. They make sheets of tinfoil of dimensions almost without limit, either by hammering and rolling, or by casting on cloth.

The establishment at Cires-sur-Vezouze replaced in 1740 the factory of Saint Quirin, and includes the workshops and melting furnaces, a portion being situated near falls of water, which are utilised as motive power. The plate glass factory at Stolberg was founded in 1853 by the Aix-la-Chapelle Company. An establishment was founded by the Company at Manheim in 1854, at the confluence of the river Neckar with the Rhone.

Amongst the objects exhibited by the Company are—

1. Plate glass, unsilvered, measuring 5·93 m. by 3·64 m., or 21·58 square metres in superficies, and 5·88 m. by 3·60 m., or 21·17 square metres.

2. Silvered mirrors, 5·90 m. by 3·68 m., surface 21·71 square metres; 5·01 m. by 3·60 m. — 18·04 square metres.

3. Moulded rough glass.

4. Coloured and aventurine glass, the latter being very beautiful.

5. Thin glass for small mirrors and photographic plates.

6. Different products, including a leaf of tinfoil, 6 m. by 4 m., for silvering the largest glasses.

There are also eight fine specimens of different sorts from the other works mentioned above, owned by the Company. The glass for the immense plates described above, was melted in one single pot, capable of containing a ton of matters in fusion, 700 to 800 kilogrammes being utilised.

The silvering of these gigantic glass plates is one of the most delicate operations. For those of twenty square metres, the sheet tin weighs two pounds per square metre; if it is any thinner, it dissolves the mercury before the operation is finished.

For a long time past I have abstained from discussing the chemical and pharmaceutical products of England, for my heart always failed me, as it was with pain that I viewed the inferiority of the English display in this class. I cannot help regretting their abstinence from our galleries, either from indifference or from other causes. This inferiority, perhaps, may be explained by the bad light in which the objects are placed, so that the daylight hardly penetrates except in a triste and gloomy ray. Several English chemists, well informed of all that has been accomplished latterly, accompanied us to this department, and found almost nothing of novelty.

THE CHEMICAL NEWS has announced that one of its oldest and most qualified collaborateurs is coming to Paris to examine the English section, and bring to light the hidden articles. I warmly applaud this step.

I am now able to give you the following list of those to whom the great prizes of the Exhibition have been awarded:—

2nd Group.—MM. *Maine*, printer and publisher at Tours; *Garnier*, photographic engraving, Paris; *Sax*, wind instruments, Paris; *Mathieu*, surgical instruments, Italy; the Reverend Father *Secchi*, meteorologic apparatus, Rome; *Eichens*, astronomical instruments, Paris; *Jacobi*, galvanoplastic work, Russia.

3rd Group—*Fourdinois*, art furniture, Paris; *The Baccarat Company*, for crystal glass, France; *Klagmann*, sculptor, Paris.

4th Group—*The City of Lyons*, tissues and silk goods.

5th Group—*Petin, Gaudet, and Co.*, steel, France; *Bessemer*, manufacture of steel, England; *Hofmann*, colours obtained from coal-tar, Berlin (Prussia); *Krupp*, steel works, Essen (Prussia); *Brazil*, *Algeria*, *British India*, *Egypt*, *Italy*, and the *Ottoman Empire*, for cotton since 1861.

6th Group—*Creusot Company*, different machines, steam engines, etc., France; *Siemens*, gas furnaces, Berlin (Prussia); *Whitworth*, mechanical tools, England; *Viguier*, railway signals, France; *Cyrus W. Field*, Transatlantic cable, New York (United States); *Hughes*, telegraphic apparatus; *Isthmus of Suez Company*; *Kindt* and *Chaudron*, apparatus for tubbing mine shafts and sounding apparatus, Belgium; *Hofmann*, brick ovens; *Napier*, marine steam engines, Glasgow; *John Penn*, marine engines, Greenwich; *Hirn*, transmission of motive power, France; *Farcot*, steam engines, Saint Omer (France).

7th Group—*M. Pasteur*, member of the Institute, preservation of wines, France; *Henri Mares*, application of sulphur to vines; *The Emperor of Russia*, thorough-bred horses.

10th Group—*The Emperor of the French*, workmen's dwellings; *Dufresne*, mercury gilding, France.

F. MOIGNO.

(FROM OUR OWN CORRESPONDENT.)

PARIS, June 25, 1867.

WE have seen petroleum oil recommended in an English paper for the destruction of insects. The method is very efficacious, but Dr. Sacc, of Neufchâtel, in Switzerland, remarks to us that petroleum oil has a more powerful effect upon plants than upon insects; it kills them as if by fire. He saw a magnificent Norfolk Island pine (*Araucaria excelsa*) killed by being doctored with petroleum oil, applied in order to kill the insects. In this case the remedy is worse than the disease.

A young chemist, M. Bèraud, relates, in a letter to M. Dumas, how his grandfather, Etienne Bèraud, was the first, at the works of La Paille, along with Chaptal, to conceive and put into practice the continuous combustion of sulphur in leaden chambers. "One evening in the year 1795, my grandfather submitted to Chaptal the following project:—A brick furnace is to be constructed close beside the chamber. The fumes of sulphur are to pass into it by means of a leaden pipe three lines thick and a foot diameter, and to prevent the heat from melting the pipe it is to be surrounded by another lead pipe full of water, to be renewed when necessary. Chaptal made a thousand objections to this process; the draught produced in the chamber would waste a great quantity of the acid vapours, and take away all the profits of the enterprise. After a long discussion, Chaptal returned home very late; on going to bed he could not sleep, but was haunted with the idea put forward by his pupil and partner. Thinking over his objections, Chaptal found them all disappear one by one, and at last so well did he approve of the proposal that he roused his servant and sent him off to La Paille, a quarter of a league from the town. Of course he found the place shut up and silent, but, by throwing stones at the window-shutters, the man roused my grandfather, who put his head out of the window. The man then cried out—'M. Chaptal has found your idea excellent, and he begs of you to put it into execution the first thing in the morning.'" The new apparatus had such success that three years afterwards the two partners divided 265,000 fr. between them as profits. A portion of this sum was spent in the construction of new works at the Ternes, Paris.

The director of the Dieuze Salt Works, M. Paul Bouquet, and the director of the laboratory, M. W. Hoffman, nephew of the celebrated professor at Berlin, have placed at our disposal a complete memoir on the regeneration of the sulphur from soda waste, which we propose to analyse in sufficient detail to give an exact and clear idea of the whole process. Soda waste, oxidised in the air, is transformed, after a certain time, into two series of compounds; one, insoluble, consists of sulphate of lime, carbonate of lime, silicate of lime, silicate of alumina, silicate of magnesia, and sulphur.

The other is soluble, and consists of polysulphide and hydrosulphate of sulphide of calcium, polysulphide of sodium, hyposulphite of lime, hyposulphite of soda, sulphate of soda, and chloride of sodium. Left to itself, and to the action of rain, the alkaline sulphide varies greatly in strength.

On the other hand, the acid chloride of manganese contains, besides chlorides of iron and barium, free chlorine, hydrochloric acid, water, chlorides of magnesium, aluminium, cobalt, and nickel. If, in order to regenerate the sulphur, we allow the acid chloride of manganese to react upon the soda waste, or on the sulphurous vapours which proceed from it, an abundant escape takes place of sulphuretted hydrogen gas. The presence in the atmosphere of sulphuretted hydrogen caused serious ophthalmia, even when present in a small quantity, which made it necessary for the workmen to stop work for some days occasionally; also, when the quantity of gas was more considerable, the air was infected to such an extent that birds passing over the vessels in which the reaction took place, fell completely suffocated. It was, therefore, necessary to produce a combination which, whilst it separated from the soda waste all the sulphur it contained, would avoid the disengagement of sulphuretted hydrogen, or reduce it to such a degree that its presence would be no longer noxious. It has been ascertained that if the soda waste, on being removed from the lixiviating apparatus, is mixed directly with a certain proportion of sulphates of iron or manganese, these salts are transformed into sulphides. The mixture is then heaped up and left exposed to the air, and is stirred from time to time and kept wetted by a thin stream of water until the metallic sulphides, absorbing the oxygen of the air, are transformed into free sulphur and metallic peroxides. These last, in presence of an excess of sulphide of calcium, are reduced afresh into sulphides of iron and manganese, which, at the end of a short time, are again oxidised in their turn by contact with the air, and so on. The oxygen of the oxides combining with the sulphide of calcium gives rise either to hyposulphite of soda or soluble oxysulphides, the composition of which approaches nearly $CaOS$. Lastly, the sulphur, being set at liberty by successive oxidations of the metallic sulphides, combines with the sulphide of calcium to form polysulphide of calcium soluble in water.

The process is now carried on at Dieuze, and is based upon the above observation. The experience of several months has practically proved that from the 20,000 litres of chloride of manganese and the 30,000 kilos. of soda waste produced every day at the Dieuze works, 14,000 kilos. of pure sulphur can be economically obtained, together with 2,200 kilos. of sulphur in the state of sulphides, 770 kilos. of binoxide of manganese at 60 per cent., 20 kilos. of hyposulphite of lime, and 600 kilos. of sulphate of lime, which can be employed instead of kaolin in the manufacture of paper.

A very interesting lecture was given on June 22, in the great hall in the Exhibition grounds at the Champ de Mars, by Captain Craufurd, R.N., F.R.G.S., etc., on the subject of the depolarisation of iron ships, by the method invented by Mr. E. Hopkins, C E. Captain Craufurd was introduced to the assembly by the writer of this article, under whose auspices the hall was constructed. This instructive lecture was admirably delivered by Captain Craufurd—not in English, but in excellent French; and the practical experiments were conducted by the Rev. E. Hopkins, son of the inventor, and illustrated by a model of H.M. ironclad frigate *Northumberland.* Among the *savants* assembled to hear the lecture of the gallant captain we remarked Admiral Labrousse and M. Gossin, both of geographical fame. F. MOIGNO.

(FROM OUR SPECIAL CORRESPONDENT.)

YOUR correspondent, when he promised to go to Paris and communicate his views upon the Exposition, little knew the task he had undertaken!

He arrived at the moment of the advent of the sovereigns of Russia and Prussia, and, for the time, nothing was thought of in Paris but the "Grand Prix," the review, and the preparations for the entertainment at the Hôtel de Ville.

It would be out of place here to detail the grand sights at which your correspondent "assisted," and you would not care to know how near he was to the assassin when a *coup de pistolet* nearly plunged France into a state of anarchy. Let us, then, leave these interesting but unscientific details, and hire a conveyance to take us to the Exposition. But this is more easily said than done. To get a conveyance now in Paris is a feat not to be undertaken too rashly. In one of the so-called comic journals with which Paris is infested (and at whose jokes we would weep instead of laugh, if the fluids of the body were not dried up by the heat), there is a picture of a family on their knees in the street imploring a coachman to take pity on them and drive them to the Exhibition. The coachman passes on, nose in air; then wildly exclaims the father (as a last resource), "Take the hand of our daughter." From the difficulty we had in Paris to get a conveyance, we believe even that bribe would be insufficient.

The appearance of the Exhibition building from the outside is, as every one has heard, most unprepossessing. At the principal entrance you walk under an awning of dark green, powdered with the Napoleonic bees. On the left is the exquisitely decorated *salon* of the Emperor, on the right the department occupied by the Whitworth and Armstrong guns.

To those who remember the two Exhibitions in this country, especially that of 1851, the general aspect of the French building—whether we regard the interior or exterior—cannot fail to be disappointing.

The arrangement in concentric rings, large as the rings are, effectually prevents the possibility of the existence of great lines, and consequently there is no part of the building or grounds where the view is really grand or imposing. Now we contend that from the great reputation which the French have not unjustly acquired, and the experience which they have had to help them, we have a right to expect something better.

To say that the French Exhibition as a building, or the arrangements as a whole, can in any way compare with the previous English ones, is simply and obviously untrue. That there is much in the present collection superior to objects of the same class which were in the previous Exhibitions, no unprejudiced person will attempt to deny; but the advance is not so great as might have been anticipated, and of the discovery of new principles, or even really new applications of principles previously recognised, there is scarcely a trace.

To return to our remarks on the general arrangements. We all know the unmerciful manner in which almost all the details of the English Exhibitions were criticised, both at home and on the Continent. But even poor Colonel Sibthorpe never (at least, in our hearing) accused the Commissioners of sacrificing the dignity of a national undertaking with the view of finding amusement for those who were too stupid to feel an interest in the contents of the building. What would have been said if within our grounds we had allowed a music hall after the type of the Alhambra of the Oxford? and yet the present Exhibition contains a *café chantant*, where four or five young ladies sing very French songs, while their audience drink beer and smoke their cigars. What would have been said if within the grounds of either of our Exhibitions we had admitted Richardson's show? and yet in the new Exhibition gardens is a so-called *Théâtre Chinois*, where conjurors swallow swords and toss cups and balls; but we pledge our word that the entertainment of the much-lamented Richardson was decidedly more attractive than that of his French descendant.

The straining after effect evinced in sending Arabs, mounted on camels, to promenade the grounds, is upon a par in taste with the plan adopted of dressing the barmaids in the costume of the country represented by the refreshment rooms in which they display themselves. It is some comfort to our insular vanity, however, to know that the Englishwomen in the ordinary dress of the period immeasurably surpass in appearance their fantastically attired sisters of other nations.

Your correspondent (who has been repeatedly accused of an undue leaning towards French things) has no hesitation in saying that in the Paris Exhibition the dignity of a great national undertaking has been sacrificed to glitter, theatrical effect, and, above all, to the great principle of "making the war pay its expenses."

After the building is closed, the theatre and refreshment bars remain open, and the aspect of the place so much resembles that of a *Mabille* or *Maison Rouge*, that really one would scarcely be astonished at lighting upon groups illustrating the dances of all nations with a *soupçon* of *cancan*.

No unbiassed person of good taste will, we are certain, deny that in grandeur, repose, and dignity, the present French Exhibition, as regards building and arrangements, is inferior to both its English predecessors.

If we were asked what we thought the visitors generally admired most, we should unhesitatingly say the pictures. This, however, is always the case, it being obvious enough that there are more people capable of appreciating pictures than there are of comprehending machines, specimens, and objects illustrating the present state of practical science.

It was, however, decidedly an unexpected—shall we say undesired?—pleasure to meet so many old, very old friends among the pictures. It must, nevertheless, be admitted that infinitely more tact has been exercised by the judges who admitted the pictures (whatever the rejected artists may say) than has been shown by those whose province it was to select the objects considered worthy of representing the present state of chemical manufactures.

We contend that no object should be admitted into an exhibition unless it has to a greater or less extent a characteristic appearance or property. A platinum still *is* a proper object, because, although the platinum might possibly be impure, its appearance in some degree enables the spectator to form a judgment upon it, and moreover its value and beauty render it an object of interest; but cakes, bottles, and tins of blacking, no matter how good in quality, can represent no important advance in excellence, no development of an idea, and serve no purpose whatever save to show the vanity and bad taste of the exhibitor.

When we think how many beautiful works of science and art have been refused space, and how many more have never been sent, owing to the modesty or timidity of their inventors or makers, we cannot refrain from expressing our disgust at seeing cases filled with soda water, baking powders, and blacking.

In our next article we shall return to the description and study of the chemicals in the English department.

Paris, June 15.

PROCEEDINGS OF SOCIETIES.

A Course of Four Lectures on Spectrum Analysis with its Applications to Astronomy,* *by* William Allen Miller, *M.D., LL.D., Treasurer and V.P.R.S., Professor of Chemistry, King's College, London.*

Lecture II.

Spectra of Simple Bodies.—Spectra of Compounds.—Effect of Temperature upon each of these classes of Spectra.—Mode of Comparing Spectra with each other.—Analysis of Artificial Flames by the Spectrum.—Nature of Information thus obtained.—Discovery of New Metals by the Spectrum.

In the last lecture I brought before you three different classes of spectra—1. The spectra produced by the ignition of solid and liquid bodies, which are continuous. 2. The spectra of ignited gases, which are discontinuous, or interrupted. 3. Composite spectra, the result of the action of the spectrum of an ignited gas or vapour upon a continuous spectrum at a higher temperature which is transmitted through the gaseous spectrum. We have, therefore, 1, spectra exhibiting one continuous shaded band of varying colour, from red, on the one hand, to violet on the other; 2, spectra in which certain colours only are present, each band of colour being perfectly definite, and referable to the particular substance by which it is produced; and 3, we have absorption spectra produced by the superposition of this second class of spectra upon the first.

I purpose to-day to confine our attention chiefly to those spectra which are furnished by the incandescence of gaseous matter under different conditions—different especially as regards temperature; for the study of differences of this kind is particularly necessary to enable us correctly to interpret the changes going on in objects at a distance.

It is a remarkable, but, at the same time, not, perhaps, on consideration, a very surprising fact, that the same substance in the liquid or solid condition should give out a very different spectrum from that which it exhibits in the gaseous state. The particles of which bodies consist in the solid or liquid form are fettered, so to speak, by association with each other. Consequently, the vibrations to which they give rise are, of necessity, of a more composite order than those which would be produced by the same substance if it were converted into the gaseous condition, where its particles not only have no mutual attraction, but are powerfully self-repulsive. These ultimate particles or atoms, in the case of simple bodies—molecules in the case of compound bodies—by the fact of their being raised in temperature, acquire motions of their own, which they are able to communicate to the other; and by these motions they occasion in us the sensation of light.

---

* Reported specially for this paper, and revised by the author.

I shall, for the purpose of fixing our ideas, project upon the screen before you, in the first place, two or three gaseous spectra of elementary metallic bodies which appear to exist in the atmosphere of the sun. These metals will be, successively, iron, nickel, and chromium. The proportion of iron in the atmosphere of the sun, as we shall see on a future occasion, is very considerable. It is also probable, but not absolutely certain, that nickel is there; and there appears to be no doubt that chromium is present. Iron, at first, will give a comparatively feeble spectrum. As the temperature rises, the particles of the iron will become more intensely incandescent, and the spectrum of the metal will proportionately increase in brilliancy. Iron is a metal which requires an extremely high temperature for its volatilisation; and therefore, until the charcoal points have become fully ignited, the bands are apt to appear more fitfully than is the case with more volatile metals, such as zinc and thallium, and some others which we have had occasion to examine already. The bright bands which are here prominent will be some of those to which I shall have to call your attention hereafter when we consider them in relation to the sun's spectrum. As the iron has now disappeared, we will introduce another magnetic metal—nickel. The spectrum of nickel is one in which we have certain bands in the green particularly prominent, and, like iron, nickel is a metal which requires a very high temperature for its volatilisation. Each of these metals is an elementary substance, so far as we at present know, and, as you see, is capable, in the intense heat of the voltaic arc, of becoming converted into vapour. We will next examine the spectrum of chromium. The chromium bands are also very characteristic; among them you will observe a number of brilliant lines in the blue. These three metals cannot be volatilised in the heat of such a flame as the Bunsen gas flame, which is produced by burning a mixture of atmospheric air with coal gas, although it is a very hot flame, and may be used to volatilise a large number of substances. Amongst others it volatilises the metals of the earths and of the alkalies and most of their compounds; but it does not volatilise the metals which belong to the class with which we are at present engaged. The spectra produced by the ignition of the elementary bodies are different from those furnished by the compounds of the same bodies. Many of these compound substances, if heated to a temperature not sufficient to decompose them, exhibit peculiar spectra. The number of compound bodies, however, which can be so converted into vapour in a common flame without undergoing decomposition, is comparatively small. Metallic sodium has its own peculiar spectrum, which I have already shown you; there is also a spectrum of potassium equally characteristic, and these appear when the compounds of sodium and potassium are decomposed by heat without special precautions. But if you volatilise the chlorides of these substances in an atmosphere of chlorine, the characteristic spectra of these metals will disappear altogether. This is an experiment that I do not venture to make here on account of the extremely irritating nature of the fumes. Indeed, I am not able to project upon the screen directly the spectra of compound bodies, and for a reason which will be at once understood. The temperature which is required for a sufficient ignition to enable us to project any spectrum upon the screen is exceedingly high, far beyond any that we can attain in our furnaces, so that the very act of producing a sufficient heat to render them luminous enough to be seen by a large audience would be attended with the actual separation of their constituents, and the destruction of the compounds themselves as compounds.

I shall, therefore, in order to give you some idea of the difference between the spectra of the elements and their compounds, ask you to look at a photograph representing the spectra of certain compound substances. I have selected the spectra produced by the compounds of copper, because they resist a higher temperature than most others without undergoing decomposition, and are consequently amongst those most easily observed. On this photograph you will see a representation of three spectra, placed one over the other. The uppermost is the spectrum of metallic copper; the second is the spectrum of cupric chloride, or the compound of copper with chlorine; and the third is that of cupric iodide, or the compound of copper with iodine. You will observe certain lines in the yellow and the green, which are pretty constant in them all. In the second spectrum, characterised by lines in the blue, we see the effect produced by the combination of chlorine with the copper; and this is again different from the spectrum of the iodide. When Bunsen and Kirchhoff first made their experiments upon the volatilisation of bodies in the flames upon which they experimented, they concluded that, whatever the temperature employed, the same spectrum was always produced by the same substance. That statement has since, however, been ascertained not to be absolutely correct. An elementary body may be heated through a very wide range of temperature without experiencing any change in its spectrum, but at a very high temperature new lines not previously observed often make their appearance. I am indebted to my friend, Mr. Crookes, the discoverer of thallium, for the loan of this diagram representing the spectrum of the metal at an intense heat, and also for some specimens of thallium itself. Here is a bar of thallium, the body of which I am now speaking, of between two and three pounds in weight. It is one of the rare metallic elementary bodies recently discovered by the application of this method of spectrum analysis. The ordinary spectrum of thallium exhibits a single strong band in the green; but when the electric spark is sent between two thallium wires, supported on a suitable insulating stand, if the light of this spark be examined by the spectroscope—an instrument the plan of which I shall presently have to explain—not only does the brilliant green band come out, but a series of others are produced, especially in the more refrangible part of the spectrum, in consequence of the intense heat of the electric spark. Several other bodies show the same phenomenon, and exhibit additional lines in the more refrangible portion of the spectrum when the temperature is sufficiently raised.

Lithium offers an example of this kind. This metal presents a singular characteristic line—viz., a brilliant crimson band—which is brought out at moderate temperatures; but there is another, a fainter line, in the orange, which requires a higher temperature for its development; and, lastly, a very brilliant band in the blue, which requires a still higher heat, such as that of the voltaic arc. I believe the first time this blue band was seen was in the theatre of this Institution at a lecture by Dr. Tyndall. I have here in one of these diagrams a representation of the spectrum of lithium indicating the blue line, which we shall presently see, in addition to the two lines in the red and the orange usually seen in the lithium spectrum. The orange line is, indeed, a little too bright in comparison with the other when seen by the gas flame. [The green line of thallium was produced.] That is the beautiful green line of thallium when heated in the voltaic arc; and if I could produce a sufficiently intense heat, by sending an electric spark between wires of this metal, to project the light on the screen, a large number of other lines, which are not now visible, would be developed in the still higher temperature thus obtained. Although in the voltaic arc we have a most intense heat, the temperature is not sufficient to cause the thallium to vibrate in such a way as to produce more than a single line. The lithium at the same temperature will acquire the power of producing an additional number of vibrations of increased frequency, so that we shall have at least three distinct bands—a band in the red, a band in the orange, and another in the blue. [Lithium spectrum shown.]

Hitherto I have taken the substances in their metallic state, but I wish to show you, in the next place, that if we take certain bodies in their compound condition we may separate their constituents from each other in the flame of the voltaic arc. For instance, if, instead of taking metallic barium, I take a compound of barium with chlorine, and heat that strongly in the lamp, the chlorine and the barium at that very elevated temperature will be separated from each other; the barium will be converted into vapour, and we shall obtain from the metal its characteristic series of bands, the chlorine spectrum being so faint as to elude our observation under these circumstances. [Barium spectrum from chloride of barium shown.] I must request you to bear in mind the position of these bands, as I am about to take another compound of barium in order to demonstrate the fact that we are here really dealing with barium itself. We before had the chloride. Now I take the carbonate of the same substance, and this carbonate will at the same temperature be resolved into barium on the one hand, which is the glowing gas from which that spectrum was produced, and into other bodies which give out comparatively little light, and which, therefore, occasion no interference with the results. [Spectrum of carbonate of barium shown.] You see the spectrum is not quite so bright as the last, for the reason that the carbonate is not a body which is so completely and easily volatilisable as the chloride. The chloride is a substance which, like most chlorides, is readily volatilised by a moderate heat. The carbonate is a body which, at a high temperature, becomes decomposed. It gives off its carbonic acid and produces baryta, and that baryta, in the focus of heat which we have here, is undergoing decomposition. Its oxygen is being separated from it just as, when oxide of mercury is moderately heated in a spirit of flame, we can separate that into its components—mercury on the one hand, and oxygen on the other. So it is here with baryta; in the intense heat of the voltaic arc, the barium and the oxygen are becoming separated from each other.

I want you, then, to draw a distinction—for it is a very important one—between the spectra of compounds and the spectra of simple bodies. It has been observed that the spectrum of a compound body generally exhibits a series of broad bands, whilst in the case of elementary bodies the characteristic spectra consist of sharp, narrow, bright lines.

I stated just now that when compound bodies were decomposed in the voltaic arc, their gaseous constituents, as they disappeared, produced little or no effect upon the spectrum; but you are not from that to conclude that a gaseous body—I mean a permanently gaseous body, such as oxygen or nitrogen—is not capable of producing a spectrum. It does give a spectrum, but one of very much less brilliancy and intensity of light than metallic bodies such as I have been showing you. I wish to make this manifest, but I cannot throw the spectra of these gases on the screen. They are so very faint that, if I were to attempt to produce them, they would be invisible at a distance. But I must show you an ingenious way in which this difficulty has been overcome by Plücker, who has succeeded in obtaining such spectra in a form in which he could analyse their light by the prism; and thus he has not only been able to distinguish one gaseous body from another, but even to measure the distances between the different lines of each and make maps of the spectra of these various bodies. Here I have four glass tubes, each containing a different elementary gas. These tubes have been made in a particular manner, in order that we may be able sufficiently to concentrate the heat of the electric spark in its passage through them to render the gas luminous. Each of these tubes consists of two somewhat wide portions separated by a narrow thermometer-like tube in the middle. At each end is a platinum wire melted into the glass, and there is a narrow tube at the side for the purpose of introducing gas, and then removing more or less of it, as may be necessary, by connecting this tube with an air-pump. After the glass tube has been exhausted sufficiently it is melted off, and the vessel remains permanently charged with a quantity of gas for examination. When the experiment is to be made, the platinum wires are connected with the terminals of the secondary wire of a Ruhmkorff's coil, from which the induction spark is transmitted through the tube. You will see how different the appearance of the spark is when it passes through the wide part of the tube from that which it exhibits in passing through the narrow portion. In the latter it is much more brilliant, and the temperature is higher. It was by an arrangement of this kind that Plücker was enabled to increase the brilliancy of these spectra sufficiently to analyse their light by means of a prism. Here are hydrogen, nitrogen, chlorine, and iodine. You will observe that I am showing you the entire light caused by passing the spark through these gases. Every one of these has a special light of its own. Here is the red light of hydrogen; the violet light of nitrogen; the third tube shows the peculiar light of chlorine, while the light of iodine in the fourth is quite different from any of the others. Each of these luminous lines, when viewed through a prism, is seen to consist of bright lines, as in the case of the metals. I cannot show you their spectra; if I could, I should be very glad to do so, because they are exceedingly beautiful.

Here let me say that, beautiful and brilliant as are the spectra which I throw upon the screen, they are totally unfitted in this form for examination from a philosophical point of view. The object of these experiments at the present time is to show distinctly and in a broad way the differences which exist in the spectra of different elements; but the philosopher, in examining these in his closet, has not merely to see that they are different, but he has to measure with great precision the intervals between each of these bars of light; for you will see that here, as in the notes of music, each one of these lines has its own special position in the scale, and we must know exactly what that position is in order to be able to recognise it again, so as to connect it with the substance by which it is occasioned. The eye has no means of comparing these differences as the ear compares sounds, but we are obliged by angular measures to determine the position of these lines with regard to certain fixed points. More of that, however, by-and-by.

Before I quit this part of our subject, I wish to show you that in particular cases the same gas may give two different spectra. If you send an electric spark through one of these exhausted tubes of nitrogen at a low temperature, you will obtain a spectrum of a particular kind, but the same gas will exhibit at a higher temperature a spectrum which is quite different. This is one of the most important discoveries with reference to gaseous spectra which Plücker has made. Here is a nitrogen tube arranged on a whirling table for imparting to it a rapid rotary motion. Nitrogen is a substance which, at a low temperature, emits a golden yellow light, and this, when examined by the prism, is seen to consist of a series of bands in the less refrangible part of the spectrum. If the temperature is raised—as by sending a spark from a large Leyden jar through the tube—the light becomes of a bluish or violet colour, and then the character of the spectrum is seen to be entirely altered. I can only show the alteration in the colour and duration of the light at the two different temperatures. But as I cannot show you the spectra of the gases upon the screen, I have endeavoured to obtain a substitute by employing the aid of the photographer; and if this photograph be placed before the lamp we shall be able to project upon the screen a representation of the different spectra which Plücker has figured. I shall give you first the series of bands which are produced at low temperatures, directing your attention first to nitrogen, a material which is of special interest to us, inasmuch as it is the most abundant constituent in our atmosphere. You will observe particularly the spectrum of nitrogen, and notice the particular way in which the bands are distributed. It is found that these bands are made up of fine lines closely aggregated together. The spectrum becomes more feeble towards the refrangible end, and at this point in the violet it suddenly ceases. This is the nitrogen spectrum at the lowest temperature. Plücker and Hittorf (who made their experiments together) call this the nitrogen spectrum of the first order. I now wish to show you, in contrast to these lines, the effect which is produced by sending through the same gas a spark at a high temperature; here we have a series of brilliant bands so produced, forming a spectrum quite different from that of the same gas at a lower temperature. So also in the case of sulphur the spectrum at a high temperature is of a very different nature from that which the same body exhibits at a lower temperature. This is true also of selenium, though I have not the spectrum of selenium at the lower temperature to exhibit to you. These cases, in which the character of the spectrum changes with the temperature, are the exceptions. In the case of oxygen there is no such change, neither is there in the case of phosphorus, chlorine, iodine, bromine, and arsenicum.

These differences are very important when viewed theoretically, though as yet we have no satisfactory explanation of them. It has been supposed that where two spectra occur the bands formed at a low temperature are produced by a substance which is really different from that which gives rise to the bands which are given out by what appears to be the same body at an intense heat. It has been conjectured, though it is by no means proved, that substances which, like nitrogen, sulphur, and selenium, give two different spectra, are not elementrary bodies, but that at the high temperature they are actually separated into their components, just as we recently separated chlorine from barium, and carbonic acid and oxygen from the same metal. But this conclusion is by no means well established, because it is seen that the moment we cease to pass the electric spark, the whole thing is as it was before; and if the substance has been decomposed by the intense heat, it has been as instantly recomposed on the diminution of temperature. Professor Stokes has suggested that the degree of rapidity in the vibration of the particles of the substance is connected with the different duration of the electric discharge in the two cases, and that a higher intensity of the electric spark gives to the nitrogen, for instance, the power of producing a higher series of vibrations than it can furnish when heated for a longer period to a lower degree. At present, however, that is a point for further investigation. We do not know why it should be that certain elements, if they be elements, should be thus altered, and certain others should not experience a like change under circumstances apparently similar. It is, however, an extremely curious fact, and has an important bearing upon the application of observations of this nature to the interpretation of astronomical and other phenomena.

There is another fact with regard to the spectra of gases which, as I am now upon that subject, I may mention here. Plücker observes that, although in the case of solid bodies you may gradually distinguish the presence of small quantities in admixture with others, it is not easy to do so in the case of gases. You may have a notable quantity of one gas added to another, and yet the spectrum will be only that of the predominant gas. It is not so in the case of solids. For instance, if you heat an alloy of gold and silver by the electric spark, the gold gives a spectrum in which you have also the characteristic lines of silver superadded, although the proportion of silver may not exceed one part in a hundred.

I wish to show you, if I can, the effect that is produced by examining two spectra at the same time. My object now is to give an idea of the principle upon which two different spectra are compared with each other. You must, if you please, be indulgent to me if I should not succeed, because I believe this is the first time this has been attempted before a public audience. I have here two lanterns, and I wish so to arrange them as to throw upon the screen at the same instant two spectra passing through the same lens and the same prisms. [The spectra were produced as desired.] These are the spectra of lithium and of strontium; and I have selected these two, because in each case the colour they communicate to flame is so similar that they are not capable of being distinguished from each other, if viewed without the aid of the prism. Both bodies tinge the flame of a brilliant red colour. But by means of the apparatus which we have here, we see at once that the position of the lines in the two cases is quite different. We have the crimson line of the lithium on the edge of the screen. Then we get the orange line and the blue band as the temperature rises, and you will observe that there is a blue band given by the strontium, very near the same position as that of the lithium line. It is so near that when it was observed for the first time in this theatre the remark was made, "Oh! that must be a mistake: you have taken strontium instead of lithium!" But you see when we compare the two, there is no doubt whatever about the difference. Mr. Fox Talbot was the first to point out the fact, more than thirty years ago, that lithium and strontium compounds could be immediately distinguished by the aid of the prism.

The apparatus which we use for the purpose of comparing spectra for philosophical purposes is not liable to any of the uncertainty which an extempore arrangement for projection on the screen is liable to entail from the overlapping of the two spectra. In the spectroscope, when properly arranged, the two spectra are presented to each other edge to edge with the greatest possible accuracy, and I must now endeavour to show to you how it is that this measuring apparatus is used.

We want, for example, to make an examination of the residue of a water which has been boiled down, and we wish to ascertain if, among other things, there is any strontium present in the salts. For this purpose we make an experiment precisely similar in principle to that which I made just now upon the screen. We take a salt of strontium, and we arrange it so that, by means of the apparatus at our disposal, we can transmit the light from the strontium flame through the instrument. It enters the tube at a narrow slit, and passes along it until it falls upon a lens. Placed at just such a distance from the slit as to render the beam of light parallel, the sheaf of parallel rays immediately falls upon the prism behind the lens; and when the light comes out on the other side of the prism, it is separated into the coloured bands of strontium. The observer does not throw these upon a screen like the one we have been using, but upon a far more sensitive screen at the back of his eye—the retina. To bring these lines to a focus, there is a small telescope arranged behind the prism, fitted with a sliding tube for adjusting the focal distance. The light from the other flame also passes through the same slit. If I introduce a little salt from some of the Bath waters, for example, into this flame, I immediately colour it. We place the second flame opposite to a small right-angled prism, which is so small that at a distance you do not see it in the instrument; but it is so arranged that it shall cover just half the slit. In this case the prism is used simply as a reflector, which directs the beam down the axis of the tube. We have, then, two beams passing through the same prism and the same telescope, and falling upon the eye at the same moment. They are so adjusted, however, that their spectra shall meet edge to edge. If we do this, then we have a means of making the spectrum of the strontium compare itself with that of the substance we place in the second flame.

If I take, as I will do now, a little of the residue from the Bath water, and make its spectrum fall upon the screen, we shall have a very complex image. There is the yellow line of sodium; there are green bands; I believe there is a little strontium; and there are the bands of calcium. Here is a line which is very like the lithium line. We will put some lithium into the other lamp, and see whether that gives the same line. We can compare spectra in this way one with the other; and if the bodies we introduced into the second flame are present in the original substance which is being examined, certain lines of its spectrum will run into each of the lines of the spectrum with which it is being compared, thus proving that the body compared is present in the original substance. In other words, we take a substance the composition of which is known to us, and we compare its spectrum with the spectrum of a body the composition of which is unknown to us.

Each of the earths has a spectrum of its own, which I would show you if time allowed, but as that is not the case, I must make the best approach to it that I can by exhibiting a photograph of the spectra of those bodies.

This is the characteristic line of potassium—a double line in the red. Then there is a diffused light in the middle, and here we have a blue or violet line near the most refrangible extremity, indicating potassium. Potassium is not distinguishable in such small quantities as some other metals. Here is the spectrum of rubidium, a metal which was discovered by means of this method of analysis. Bunsen was examining the water of the Durkheim spring, and he found he had a double red line which he had not seen before, and some lines in the blue which he had also not seen before. These were the lines of substances which he had not previously met with; and although in the original water only between three and four grains of the substances were present in a ton of water, yet, relying upon the accuracy of the indications which he had obtained in the spectrum, he procured a large quantity of the water, boiled it down, and succeeded in isolating these two bodies. One of them he called rubidium, from the occurrence of these red lines, and the other cæsium, so named from the occurrence of two bright lines in blue. In addition to these, two other metals have also been discovered by the aid of the prism; one of them—thallium—I have already mentioned, and you have seen the green line by the occurrence of which the metal was discovered by Mr. Crookes as he was examining a particular substance, of which he possessed but a small quantity. The difficulty then was, first, to find out in what minerals it existed, and next to devise chemical means of obtaining it. These difficulties have been overcome, and it can now be procured in considerable quantities. I have seen masses of it weighing thirty pounds. I have quite recently heard that carbonate of thallium has been introduced by M. Lamy into the preparation of glass, which is said to be superior to any hitherto used for optical purposes.

The short remainder of the hour shall be devoted to the examination of the spectra of these metals, which were originally discovered by the aid of the spectra themselves. We will first project upon the screen that of cæsium. You will probably see several lines, but the characteristic lines are those two blue lines now visible, one of them considerably brighter than the other. These are the lines more particularly distinguishable at low temperatures. There are also a number of lines in the red. In showing you these bodies in the voltaic arc, I am working under considerable disadvantage, because, at so high a temperature, the spectra are much less simple than they are at lower temperatures. At high temperatures many of these bodies, as I have said, acquire the power of vibrating with different degrees of velocity, in consequence of which additional bands corresponding to these new velocities of vibration are developed at a high temperature, but they do not lose the power of vibrating with the definite velocities which they acquired at a lower temperature; they therefore preserve the bands originally seen, as well as those produced by the intense heat applied.

We will now throw upon the screen the rubidium spectrum, using the chloride of the metal. In this case the chlorine is separated from the rubidium. If the spectrum is a good one, we shall have a double red line upon the less refrangible edge of the spectrum. Here is the rubidium line, accompanied by the paler bands in the blue. The double red line is the characteristic portion to which the body owes its name, from *rubidus*, dark red. This is very different from the spectrum of cæsium, where the blue lines were particularly prominent. The brightness of the blue lines in rubidium is not to be compared with that of the line in the red.

I shall conclude by showing you one of the latest fruits of spectrum analysis—a substance characterised by two remarkable lines in the blue. The name of "indium" has been given to it, because it gives a light of an indigo-blue colour. These bands are at the violet end. Here is the spectrum of this body. I am indebted to an old friend, Professor Varrentrapp, for this sample of indium, who has sacrificed half his specimen in order that I might be enabled to show you these bands. It is a substance scarcely to be obtained, although in the Paris Exhibition there is a mass of upwards of a pound weight of it, but it is there at present in prison as an exhibit.

ROYAL DUBLIN SOCIETY.*

At the last evening meeting of the Royal Dublin Society, Dr. Emerson Reynolds read a paper upon "*An Isomer of Sulphocyanogen.*" If the new body which he has discovered proves, on investigation, to be really an isomer of the theoretical radical, Scy, the communication will be one of the most important contributions received for some time in connexion with organic chemistry. The author, having referred to the fact of sulphocyanogen never having been isolated, dwelt at some length upon the different views that had been taken by workers with the subject, particularly as regards the composition of the sulphocyanides. These views may be enumerated in a few words. 1. We have the radical theory. In this theory, the existence of the salt-radical, CyS, is admitted, and we may look upon the ammonium salt as NH_4,C_2NS_2. This molecular arrangement is the one that is generally accepted. 2. The composition may be viewed as a sulphide of ammonium combined with sulphide of cyanogen, thus—NH_4S,C_2NS. 3. The body may be viewed as sulpheretted urea, or as a sulphocarbamide. The relation to urea is represented in the following formulæ:—

$C_2N_2H_4S_2$	$C_2N_2H_4O_2$
Hydrosulphocyanic acid.	Urea.

Gladstone (*vide* Watts's Dictionary, vol. v. page 505) has also noticed that sulphocyanic acid, together with urea (carbamide), is formed by the action of sulphuretted hydrogen on ammonio-cupric fulminate. Dr. Reynolds referred to all these views, but stated that the first was the accepted one.

Now, when sulphocyanide of ammonium is submitted to destructive distillation, it is split up, according to Liebig, into bisulphide of carbon, sulphuretted hydrogen, ammonia, and a residual substance, which that chemist has named melam. This latter substance is afterwards converted into hydromellone—

$$8(NH_4,C_2NS_2)=4CS_2+8HS+5NH_3+\underset{\text{Melam.}}{C_{12}N_{11}H_9}.$$

$$C_{12}N_{11}H_9={}_2NH_3+\underset{\text{Hydromellone.}}{C_{12}N_9H_3}.$$

When, in the presence of water, sulphocyanide of ammonium is submitted to the action of heat, Dr. Reynolds says that it gives

$$NH_4,C_2NS_2+HO=\underbrace{C_2NS_2H}_{\text{Hydrosulphocyanic acid.}}+NH_4O.$$

But he finds that heat, in the absence of water, produces

$$NH_4,C_2NS_2=NH_3+H+\underset{\text{Isomer.}}{C_2NS_2}.$$

The latter is purified by recrystallisation. It is a very stable compound, which will bear a considerable temperature without decomposition. The analysis gave figures that corresponded to C_2NS_2.

The following compounds were described:—

Bichloride of platinum gives a red crystalline precipitate, having the following composition—$C_2NS_2,PtCl_2$. It will be

---

* Specially reported for the Chemical News, by Charles R. C. Tichborne, F. C. S., etc.

seen at once that this compound does not follow the type of the ammonium salt, but accords with the composition of urea.

Nitrate of silver forms a compound, a direct combination of the salt with the isomer.

There is also a mercurial salt, $C_2NS_2,HgCl_2$.

The author said, in conclusion, that we might naturally expect to find an isomer of sulphocyanogen, as such changes seem to be a natural property of the cyanogen compounds. Thus, he gave as instances the three chlorides of cyanogen, and the paracyanogen procured on submitting cyanide of mercury to destructive distillation.

As the author used the old notation, we do so in our report.

QUEKETT MICROSCOPICAL CLUB.

Friday, May 24, 1867.

Mr. Ernest Hart, *President, in the Chair.*

The ordinary monthly meeting was held at University College.

A paper was read by Mr. M. C. Cooke "*On Binocular Vision.*"

The **President** read a paper "*On the Minute Structure of the Iris and Ciliary Muscle,*" in the course of which he demonstrated the structure and direction of the ciliary or accommodative muscle of the eye in man, ruminants, and birds, and showed that there are presented no circular or sphinctral fibres in the latter, and discredited their existence in the former. The paper was illustrated with enlarged diagrams, and numerous injected specimens under the microscope. The meeting, which was fully attended, terminated with a *conversazione.* Ten members were elected.

ACADEMY OF SCIENCES.

May 27, 1867.

M. L. D. **Girard** presented and described a new ball governor, giving perfect isochronism and acting instantaneously upon the steam valve. He maintains the balls in any position by giving to the motor a constant velocity, and also an angular velocity equally constant. He proves by calculation that the four-balled regulator, when in equilibrium, is isochronous; that it does not follow the mathematical laws of the conical pendulum of Watt; that it can be applied without any change to all machines.

M. Felix de Luca placed upon the table in the name of his brother Dominique de Luca, director of the ophthalmic section of the "incurable" hospital at Naples, a note "*On the Employment of Sulphate of Soda in the Treatment of Spots on the Cornea.*" After having mentioned the inefficacy, inconvenience, and at the same time the dangers of the known methods—laudanum, alcoholic or tannic liquids, etc.—he thinks that crystallised sulphate of soda, by reason of the property it possesses of maintaining in solution the fibrine of the blood, can exercise a favourable action on spots in the cornea. In the first experiments use was made of an aqueous solution of sulphate of soda saturated in the cold; it was let fall drop by drop on the eyeball. The spots diminish in extent, but with an excessive slowness. For the solution M. de Luca substitutes the sulphate reduced to a fine powder, which he lets fall by pinches on the eye twice a day, the head resting nearly horizontal. The salt is dissolved by the humours of the eye, at the same time producing an agreeable sensation of cold. At the end of a few days the spots commence to disappear, and the patients, who could not see at all, distinguish the movements of the hands and fingers, and the blindness soon ceases.

CHEMICAL SOCIETY.

Thursday, June 6, 1867.

Dr. A. W. Williamson, F.R.S., *Vice-President, in the Chair.*

The minutes of the previous meeting were read and confirmed.

Sir Benjamin C. Brodie, Bart., Professor of Chemistry in the University of Oxford, then delivered the following lecture:—

"*On the Mode of Representation afforded by the Chemical Calculus, as contrasted with the Atomic Theory.*"

Mr. President,—I feel that I have undertaken this evening a truly difficult task, which is to give to the Chemical Society, in the brief space of one hour, an account of a somewhat abstruse and difficult subject, the exact comprehension of which requires that it should be minutely considered in all its details. I should not, however, shrink from this, if I did not feel that the subject is really before those who are most competent to judge of it, in a somewhat imperfect form; that I have as yet offered to the chemical world the first part only of the method of which I am about to speak; and that this method will be much better comprehended, both from a mathematical and chemical point of view, when you have before you the subsequent parts which I hope to present hereafter.

I am to speak of a method of representing the facts of chemistry, which is fundamentally different from the method at present in use. Let me say a few words upon the past history of chemical theories.

I believe that theory is essential to the existence of chemistry. The birth of the science was inaugurated by the construction of a definite theory of chemistry—the first theory which had ever been proposed, and which sought to give a definite and rational account of the facts of the science. This theory was the once world-famous doctrine of Phlogiston. In this theory the facts of chemistry were explained by the agency of a subtle, hypothetical, all-prevading principle, by the transference of which, from one chemical substance to another, it was assumed the facts of chemistry were correctly accounted for. It is easy, from our present point of view, to pass critical remarks upon the doctrine of Phlogiston, but it is not quite so easy really to comprehend that doctrine, and to put ourselves in the position of those great chemists who worked and who studied through its agency. If ever any one was tempted to speak slightingly of the doctrine of Phlogiston, let him remember that through the instrumentality of this doctrine the great discoverer of chlorine, the chemist Scheele, worked. Let him remember that the exact mind of Cavendish was contented with this doctrine. Let him remember again that the illustrious Priestley, that transcendentally inventive genius, in possession of this doctrine, made the great discovery of oxygen; and that not only was he then content with this doctrine, but that he died a firm believer in and adherent to it. However, the doctrine of Phlogiston, like many human things, was destined to pass away,—Lavoisier shattered Phlogiston. For no inconsiderable period after this, chemists appear to have worked, if I may so say, without a theory; that is to say, that, as during the long alchemical ages chemists were occupied in collecting together those facts which were afterwards to be embodied in the theory of Phlogiston; so for a period of above thirty or forty years—that is to say, from the time of Lavoisier to the time of Dalton—chemists were employed in collecting together that exacter system of facts which was to form the basis of a far wider, a far more comprehensive, and a far nobler theory, namely, the great atomic doctrine. However, Davy appears to have worked and to have made his great discoveries without a theory. Davy never admitted the atomic theory, but rested content simply with the facts of numerical analysis.

In the year 1808 there appeared that famous book, "A New System of Chemical Philosophy," which contained the germs—indeed, I may say, almost the full development—of the atomic theory itself. In this atomic doctrine Dalton took up the conception of combination, which was introduced into the science by means of the theory of Phlogiston. He took up that doctrine of combination, and moulded it into a new and a more definite form. It would be useless for me, before the Chemical Society, to dwell upon the atomic theory. It is a theory with which every one is familiar, for every chemist of this day has worked with that theory, has conceived his science from the point of view of that theory; and, indeed, I believe it is, in the opinion of many, almost impossible that that doctrine should ever fall to the ground. This doctrine of Dalton, however, was a doctrine far more audacious than that of Stahl. In the theory of Phlogiston, Stahl considered that he had palpable evidence of the transference of his Phlogiston from chemical system to chemical system; but Dalton told us that this notion of the continuity of matter—that obvious fact which our senses teach us—was simply an illusion of the senses, and that, if only we could see things aright, we should see that this world, which appears to us so connected and so continuous, was really made up of an almost infinite number of disjointed fragments.

From the point of view of the atomic theory, I say, chemists have worked for a period now of about sixty years, and the progress of chemical theory has consisted in the almost constant and unremitting development of this doctrine. I cannot say, however, that this has been an unremitting progress. It has rather been a succession of events. System has followed system, doctrine has followed doctrine; but these doctrines have, one after another, fallen to the ground. We have had but little that is permanent, and at the present moment the theory of chemistry is built upon the ruin of other theories. Now, no one can have more respect or more admiration for these great ideas, which were thus ushered into the science by Dalton, than I myself have. It cannot be necessary for me to express to this Society the admiration which I feel for that theory; but, nevertheless, I cannot but say that I think the atomic doctrine has proved itself inadequate to deal with the complicated system of chemical facts, which has been brought to light by the efforts of modern chemists. I do not think that the atomic theory has succeeded in constructing an adequate, a worthy, or even a useful representation of those facts. I say that for sixty years the united efforts of chemists, including many of the most able men in the world, have been devoted to the development of this doctrine, and they have formed their representations upon this doctrine. Now, let me read to you an account of the last modern representation of the atomic doctrine, and the chemical symbols in which the atomic doctrine has resulted. I will read to you a paragraph headed "Glyptic Formulæ;" it is given in a scientific journal. Here is the paragraph:—

"Those teachers who think, with Dr. Frankland and Dr. Crum Brown, that the fundamental facts of chemical combination may be advantageously symbolized by balls and wires, and those practical students who require tangible demonstration of such facts, will learn with pleasure that a set of models for the construction of glyptic formulæ may now be obtained for a comparatively small sum." (Much laughter.) "At first sight, the collection of bright-coloured and silvered balls suggests anything but abstract chemical truth,"——

And so on. However, I will tell you what you may get for your money:—

"There are seventy balls in all for the representation of atoms—monads, dyads, triads, tetrads, pentads, and hexads, being distinguished by the number of holes pierced in the balls. To connect these into rational formulæ"—[which, I confess I should think was a truly difficult problem]—"brass rods, straight or bent, and occasionally flexible bands are employed." (Laughter.)

And so on. However, the editor seems to have had some misgivings, for he proceeds to say,—

"Whether they are calculated to induce erroneous conceptions is a question about which much might be said."

Now, however much might be said upon this subject, I certainly am not going to say a great deal to the Society upon it; but it is truly a remarkable fact, that the atomic theory, after so many efforts, has resulted in such a symbolical representation as this. I think that great injustice is done in connecting the names of Dr. Frankland or of Dr. Crum Brown specially with such ideas as these, for I cannot but say that I think the promulgation of such ideas—even the partial reception of such views—indicates that the science must have got, somehow or another, upon a wrong track; that the science of chemistry must have got, in its modes of representation, altogether off the rules of philosophy, for it really could only be a long series of errors and of misconceptions which could have landed us in such a bathos as this.

You may, however, ask me, and with reason, "In what way, then, are we to represent the facts of chemistry, if we are not to represent them in this way? Do you mean to deal with this complicated system of facts, and to offer us no mode of representing these facts, and no mode of conceiving these facts?" Now, I certainly believe that any person who seriously attacks these ideas, is bound to show some other, and, I will say, some better way of representing the facts. I think he is bound to do this, or he should refrain from his attacks. You ask me how we are to represent the facts of the science. It is to that question that I wish to offer an answer to-night.

I say that we are to express the numerical facts of the science by means of symbols; but I attach to the term "symbol" a very special signification. We have plenty of what are called "chemical symbols" already; but these chemical symbols are not, from my point of view, symbols at all, and you will presently see why. Not only according to my ideas, but according to the ideas of most persons who consider this question, a symbol may be regarded as a mark by which we express the objects of our thoughts for the purpose of reasoning about those objects; and one which is capable of being combined with other similar marks according to certain definite laws of combination; which laws of combination are to be possible, through the interpretation of the symbol, in the subject matter which is symbolized. That is what I mean by a symbol.

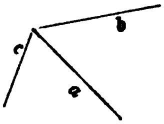
You will readily see that our present notation really can hardly be called, even in courtesy, a symbolic representation. The reason is, in the first place, that these letters are not capable of being combined with other letters, or other marks, according to any definite laws at all; and, in the second place, so far are they from having any definite signification or meaning attached to them, that every chemist thinks himself at liberty to deal with them just as he pleases, according to his fancy. Now, I say, I wish to put a restriction upon that mode of dealing with the subject, and to bring my fellow chemists and myself under some definite laws when they deal with symbols.

Symbols are of two kinds. We may have symbols of things, and we may have symbols of operations. Symbols of operations are simply symbols of what we do to things. Take a popular case; ordinary language is an imperfect symbolic system, and here we have just these two kinds of symbols. A "dog" is the symbol of a thing, and "beating," "caning," "coaxing," and so on, are the symbols of operations, or of something which we may do to a dog. We have marks by which we express things and marks by which we express what we do to things. We might also have a third kind of symbol; we might have the symbol of an operation and a thing together. Thus, if we did not wish to represent particularly what sort of animal we were going to beat, we might have a single mark for "beating an animal;" the thing and the operation being included in one.

I purpose, however, to go into a more exact kind of symbolism; but before I commence my explanations, I should like to remove one or two popular errors upon this subject. I believe there is no error more ingrained in the popular mind than that these marks $+ \; - \; \times \; =$ are the symbols of adding, subtracting, multiplying, and identification or equalization; I mean that these marks are purely arithmetical symbols, and are to be used for the purposes of arithmetic alone, and that in any other subject matter to which they are applied it is essential for us to give these symbols their arithmetical signification. If that were true, the application of symbols to the science of chemistry would simply be, from my point of view, an impossibility.

Perhaps I shall best illustrate this matter if I give you, from another subject, an example of the mode of constructing a symbol, and what we mean by a symbol. It is an example which will bring before you clearly how independent symbols are of their arithmetical meaning or interpretation. I say of their arithmetical *meaning*, not of their arithmetical *laws*, which is another thing. In ordinary algebra we denote, by the mark a, the operation of conferring upon the unit of length a certain length which we designate as a. This length we may call three feet, and the mark a will thus stand for a line three feet long. Now, if we take another symbol, b, that may indicate to us a line drawn in the same direction as a, but of another length. We will say that b is five feet. Now a tells us that we are to draw a line of a certain length; and we may say that the symbol $+ a$ means that we are to draw it in a certain direction. Now if we ask what is the meaning of $+ a + b$, this indicates to us that, having drawn a, we are to start again, and we are to draw another straight line of the length of five feet, which we call b. Or, in ordinary geometry, $+ a + b$ would symbolize to us a line, the length of which was the sum of the length of a and b, and drawn in the same direction.

I wish now to bring before you, very briefly, an illustration of how totally unnecessary this arithmetical application of the meaning of the symbol $+$, is to its algebraic meaning. We have another kind of geometry, we may say, in which the symbols a, b, c, and so on, may indicate to us not only length, but direction also; so that if we take a certain point as our starting point, the symbol $+ a$ would indicate to us that we were to start from the point a and draw the line $+$ in a certain direction—we will say towards the horizon. And b would indicate to us that we were to draw a line in another direction, and of another length; and c that we were to draw a line in a third direction, and also of another length. Thus



in short, it is open to us, if we choose to do so, to express by letters, not magnitude only, but also position.

Now, I wish you simply to see at what we arrive by following out these principles. What is the interpretation of $a + b$? a tells me to draw a line from our starting point in a certain direction and to a certain length. $a + a$ indicates that I am to make a line in the same direction as a and twice as long; in like manner — would also indicate to us the direction in which we were to draw our line relatively to the starting point. $-a$ would be a line equal in length to a, but in the opposite direction to $+a$.

Now b tells us that we are to perform upon the unit of length an operation which is to consist in drawing a line in another direction. Here is our line 
What therefore do we mean by $+a + b$? Why $+a$ tells us that we are to construct the line a. And having done that we are to go on again and construct b. That is done by beginning again at the end of the line a, and drawing a line in the direction of b, and equal in length to it, by which means we get 

If we draw the diagonal of the parallelogram of which a and b are the sides, the diagonal of that parallelogram is expressed, and properly expressed, as $a + b$ 
And I say that a line drawn through the first point, equal in length to the other diagonal of the parllelogram but in the opposite direction, is properly represented by $b - a$ 
Those two diagonal lines in the system of geometry express $a + b$ and $b - a$. The reason of this you will perceive is very obvious, for, as we all know, the diagonal line, relatively to direction and to the motion which makes it, would be the same in kind and in quantity as the motion which constitutes the lines a and b. In short, we first of all construct the line a, and then we go on again and take up the line b. The diagonal of the parallelogram is therefore properly expressed as $a + b$, but of course this diagonal is not equal in length to the sides of the parallelogram.

There is one other property I must refer to, which is very important, and comes out to us in the symbol $+$. It is, that $a + b$ is the same thing as $b + a$. Why is this? It is simply that when we go along the line in direction a, and then travel through the length of b, we arrive at the same quantity as when we go along the lines $b + a$.

In constructing any calculus or method, then, the principle to be observed, in regard to the symbols, is by no means to give to them their arithmetical meaning or interpretation, but simply to construct them properly according to the laws which they obey in arithmetic and in algebra.

To take another example, using the marks $+$ and $-$ as the simplest illustration. They may be regarded as marks which are subject to a certain system of laws, which laws are given in the following equations:—

$$+ + = +$$
$$+ - = -$$
$$- + = -$$
$$- - = +$$

If, then, you can find in any subject matter, any properties to which you may apply these symbols $+$ and $-$ consistently with this interpretation, I think you are justified in using the symbols $+$ and $-$ to express those properties.

Let me proceed to explain, very briefly, what I mean by a chemical symbol. The object, I should say, of the first part of this method is to discover a proper system by which we are to express the unit of chemical substances. I may put this in another way, and say that we wish to discover what is the nature and the number of the operations by which chemical substances are made or constructed. This is the first object of our method. I should, perhaps, limit myself a little farther, for I should say that before we begin to think about chemical substances at all we should conceive of them as all brought into the condition of perfect gases. Now, the reason of this is one which I am sure will commend itself to every chemist: it is the simplicity of the laws to which gaseous combinations are subject, which simplicity was first discovered by the great chemist Gay-Lussac. Of course we may deal with the properties of the combinations of solids and liquids, but here it is far more difficult for us to arrive at any intelligible and simple results; and, whether rightly or wrongly, before beginning to think about the nature of a chemical substance, I, for my part, always conceive it as brought into the condition of a gas. And to go a little further, and to speak a little more definitely, we shall always consider the chemical substance brought into the condition of a gas at the temperature of 0 degrees, and at a pressure of 760 millimetres. This is the sort of ideal chemical world with which we have to deal. It is a world of gases.

First let me indicate to you the definition which I will take of a unit of matter; for it is absolutely essential, before we think about matter at all, to begin with defining the unit which we are about to consider. That definition is of such great importance that I have had the words placed up before you in this diagram.

The unit of ponderable matter, is that portion of ponderable matter which, at a temperature of 0 *degrees, and at a pressure of* 760 *millimetres of mercury, occupies a space of* 1000 *cubic centimetres.*

From considering the unit of matter, I pass now to the consideration of a unit of another kind, and that is what I call the unit of space—that is, the volume of 1000 cubic centimetres. And just as, before we begin to think about chemical substances, we must bring them all theoretically to the state of gas; so, before beginning to think about the unit of chemical substances, we must begin by thinking about a unit of space. This is the fundamental conception of this method; and it is a notion which appears to me to be almost essential to any constructive chemistry at all—that is, the conception of the unit of space; let us, therefore, clearly understand what the unit of space means. Now, that there may be no doubt about it, I have brought you the unit of space [exhibiting hollow cube with glass walls, and of the dimensions above assigned to the unit of space].

You have to do something else, however, before you get the unit of space. It is indeed the space of 1000 cubic centimetres which is confined within these glass walls; but before you can get at the unit of space, you have to go a step farther, and by the process of imagination, or by the efforts of reason, you have to divest this cube of glass of weight, and take out of it all the ponderable matter which it contains, and conceive the space within the walls divested of matter altogether. Now, this unit of space is so fundamentally important to us that I shall begin by giving it a mark to itself. The mark which I give to that unit of space is, for certain good reasons which I will not explain now, the mark 1. When you see that mark, it is to recall to your mind the matter contained in the unit of space. Now, what is that matter? Why, that matter is simply no matter at all; there is no ponderable matter in it.

Perhaps, however, if I were to speak a little more exactly and precisely, I should say, for the benefit of those persons who may be more philosophically inclined, that the mark 1 is the symbol of the operation of taking the unit of space as it is. That is, take the unit of space as it is, and do nothing at all with it.

However, we must not only consider units of space, the consideration of which alone would lead us to very little, but we are going to consider the units of matter. Now, how are we to conceive a space becoming matter, or of matter getting into space—chemically, I mean? Well, I shall think of this through the aid of an operation, and I shall define by a mark the operation by which this empty unit of space is turned into a unit of ponderable matter. For example, I will take x as such a mark. This is the mark of the operation by which the unit of space becomes a unit of ponderable matter. It is the mark of a certain density which is appropriated to x, and of a certain kind which is also supposed by x. Here, then, is x, the symbol of the operation; and how are we to symbolize the performing this operation upon the unit of space? I shall do this in a natural manner by writing the letter x before the unit of space, $x1$; and that indicates to me matter of a certain density, and at 760 millimetres pressure.

How are we now to conceive a matter, double the density, but the same in kind as x? Having once conferred upon the unit of space this density, we have only to perform the operation a second time. Hence, to double the density, we have only to write x again, thus: $xx1$. This will symbolize that we confer on the unit of space a certain density, and having done that we confer that density on it again. That is, we make it double the density. $xxx1$ will mean that we give it three times the density. We can abbreviate the expressions. We need not write the x's out at length. The unit of space is 1; with the first density conferred upon it, it becomes $x1$; with double the density, $x^2 1$; and with three times the density, $x^3 1$. If you compare these operations with the symbols which express the densities, you will see that the symbols of the units of matter which we have thus constructed, stand to the numbers which express the densities of that matter, in the same relation as numbers do generally.

We will now take another kind of metter: 1, $y1$, $y^2 1$, $y^3 1$. This, again, would be a symbolised ponderable matter which would be contained in this glass box at the pressure and temperature indicated, of the kind indicated by y, and of the density indicated by the number of units of y. You will see this more obviously when we come to speak of the symbols of chemical substances.

If we proceed farther upon the same principles, we come to consider what is the symbol of units of space containing two kinds of matter. Well, on the same principles, you see, we have $xy1$ as the symbol of the unit of space filled with the matter of x, and also filled with the matter of y; that is to say, having the density xy, the sum of the densities of x and y. And of course we can, in this way, symbolize also the unit of space filled with the matters x and y in various proportions.

You will see that there is a real analogy between the symbols which I am here employing, and the symbols which I used just now in my illustration derived from double algebra; for just as the symbols of double algebra indicate to us not only the length of a line, but also its direction or position, so these chemical symbols indicate to us not only the weight, but also the kind of matter. You are not to confound them with the numbers which express the densities, or the letters by which we might express those numbers; but they are, I say, symbols which express to us, at one and the same time, the nature of the matter and the density of the matter, having a double signification of this kind.

Before we go further, let me say a word about the nature of this operation. I am here symbolizing the unit of matter by the symbols of the operation by which the unit of matter is made. But what is that operation?

Well, speaking generally, I may say, without entering into too nice logical distinctions, that it is an operation which every chemist knows better than any other physical operation. It is the operation of combination. That is what x is, and what y is. They are operations of combination. We are getting thus at a definition of our unit in terms perhaps more in accordance with our ordinary language. We will call the matter of x, A, and the matter of y, B; and the matter of unit of space, merely o. That is always definite. What, then, does x stand for, considered from the point of view of combination? It is the operation of combining the matter A with any substance which we please to write after the symbol of the letter. Similarly, y is the symbol of combining the matter B. Then we may call 1 the symbol of no matter; it is the symbol of the unit of space, which has no matter. $x1$ tells us we are to take A and combine it with the matter of unit of space. The result of that is to constitute the matter A. Having done that, I write y to it ($xy1$). That tells me to take the matter B and combine that also with the matter of the unit of space. If you do that, the result is the matter of A combined with the matter of B. These are the operations. Do not imagine there is anything mysterious about these terms. They are the operations about which you think every day of your life; and, I say, if you want to think philosophically about chemistry, you must embody in your symbol the very thing which you are thinking about, namely, the operation of combination itself.

I must not seek to explain to you now the process or method by which we arrive at the symbols of chemical substances, for to explain the process on the board, and to do it any justice, would occupy far more time than is at my disposal. You must allow me now simply to explain what we mean by the symbol of chemical substances (I mean in special cases), and then to consider the general results to which this mode of representation conducts us.

As to the mode of constructing these symbols, it is based in the most absolute way upon facts. We do not construct a symbol at all. We simply look for the symbol of matter and we find it. Where are we to look for the symbols of a chemical substance? Why, plainly to the symbols of matter in the gaseous condition: and where are we to look for the symbols of the operations by which units of matter are made? Why, plainly in the facts of combination. That is the source whence you are to deduce the symbol: it is the fact of combination itself. The facts in gaseous combinations are such as these:—2 volumes of hydrochloric acid consist of the same ponderable matter as 1 vol. of hydrogen and 1 vol. of chlorine. 2 vols. of gaseous water consist of the same ponderable matter as 2 vols. of hydrogen and 1 vol. of oxygen. Again (I will now put it in my way), 2 units of ammonia consist of the same ponderable matter as 3 units of hydrogen and 1 unit of nitrogen. These are the facts, and chemistry supplies us with a vast, but not an infinite number, of such facts. The method which I have ventured to give is simply a method of expressing the facts of the equation in the symbol of the substance. It is simply and purely a method of taking an equation and of embodying in the symbol the facts of the equation. Through the facts of the equation we construct the symbols of the units of ponderable matter. We then take the symbols out of the equations, and we thus separate and analyse the facts one from the other. It is simply an analysis of facts of a peculiar kind.

I have constructed some tables expressive of the general nature of the conclusions, at which we arrive through the aid of this method, as to the composition of these units of matter. I have had a good many of these symbols written out, for really it is easier for you, by looking at these tables, to see the general results which we arrive at by this method, than it would be for me to enter into a long explanation of the process. Here you see are the symbols of the chemical substances. We start with the symbol of the unit of space.

Symbols of the Units of Chemical Substances.

Unit of space	1
Hydrogen	α
Oxygen	ξ^2
Water	$\alpha\xi$
Peroxide of Hydrogen	$\alpha\xi^2$
Sulphur	θ^2
Protosulphide of Hydrogen	$\alpha\theta$
Bisulphide of Hydrogen	$\alpha\theta^2$
Sulphurous Anhydride	$\theta\xi^2$
Sulphuric Anhydride	$\theta\xi^3$
Sulphurous Acid	$\alpha\theta\xi^2$
Sulphuric Acid	$\alpha\theta\xi^4$
Chlorine	$\alpha\chi^2$
Hydrochloric Acid	$\alpha\chi$
Hypochlorous Acid	$\alpha\chi\xi$
Chlorous Acid	$\alpha\chi\xi^2$
Chlorosulphurous Acid	$\alpha\chi^2\theta\xi$
Hypochlorosulphurous Acid	$\alpha\chi\theta\xi^2$
Chlorosulphuric Acid	$\alpha\chi^2\theta\xi^2$
Iodine	$\alpha\omega^2$
Bromine	$\alpha\beta^2$

In the next table is another system of symbols, those of the combination of carbon, hydrogen, and two or three other elements.

Carbon	κ^2
Acetylene	$\alpha\kappa^2$
Marsh Gas	$\alpha^2\kappa$
Olefiant Gas	$\alpha^2\kappa^2$
Carbonic Oxide	$\kappa\xi$
Carbonic Acid	$\kappa\xi^2$
Alcohol	$\alpha^3\kappa^2\xi$
Ether	$\alpha^5\kappa^4\xi$
Glycol	$\alpha^3\kappa^2\xi^2$
Glycerine	$\alpha^4\kappa^3\xi^3$
Anhydrous Acetic Acid	$\alpha^3\kappa\xi^3$
Tetrachloride of Carbon	$\alpha^2\chi^4\kappa^2$
Chloroform	$\alpha^2\chi^3\kappa$
Chloracetic Acid	$\alpha^2\chi\kappa^2\xi^2$
Trichloracetic Acid	$\alpha^2\chi^3\kappa^2\xi^2$
Chloride of Benzoyl	$\alpha^3\chi\kappa^7\xi$
Cyanogen	$\alpha\nu^2\kappa^2$
Hydrocyanic Acid	$\alpha\nu\kappa$
Methylamine	$\alpha^3\nu\kappa$
Mercuric Ethide	$\alpha^5\kappa^4\delta$

You must regard these symbols as being chemical equations turned into another form, and divested of a certain amount of superfluous and useless matter, which we do not want now to consider or think about. Nature does not supply us with the key note to enable us to construct a definite system of chemical symbols. Nature does not tell us absolutely—though I think she does tell us probably—how we are to proceed to construct a system. In order to be able to construct a chemical system we must start with a hypothesis of some kind or other. As we go on constructing our symbols, of course our hypothesis, as we prove it, becomes a fact; but we must, at any rate, start with some hypothesis; that is to say, we must know one symbol. We may construct a complete chemical system from one symbol; and we may view all these symbols as taken from one hypothesis, combined with the facts given to us and supplied by the equation. Now, that hypothesis is this, that the symbol of the unit of hydrogen is expressed by one letter, α. That is my starting point; and I should say that the symbols which you see in the tables, as indicating chemical operations, are regarded as symbols of primary operations, that is to say, operations which you cannot resolve or decompose into any other symobls.

They are symbols of the primary operations; and when I say that the symbol of hydrogen can be expressed in chemical equations by one letter, I mean that in the changes and transformations of chemistry that unit of hydrogen is never broken up; that it moves as a whole from system to system, and that that unit of hydrogen is never decomposed or resolved into parts. The unit of hydrogen is constructed at once, by one operation. What I mean is this: imagine yourself witnessing the formation of hydrogen. To form some substances you want many operations; but to form hydrogen you want only one operation. That [striking a blow on the glass model of the unit of space] represents the formation of hydrogen,—one operation. It is one act. If we could witness chemical transformations, and nature would only become vocal tous, and indicate each combination as it occurred, by a musical note, that [again striking a blow] is what you would hear when hydrogen was formed. Now, as we go on we come to much more complex substances. Let us take oxygen. This is a substance very different indeed from hydrogen in its chemical properties; and as you can conceive of the unit of hydrogen being made at once by one operation, I say that it is impossible for you to conceive of the unit of oxygen being made by less than two operations. To return to our metaphor, when you take water and decompose it, and when you hear the oxygen go away, you ought to hear two notes, like this [striking two blows in close succession]. That is what I mean by saying that oxygen is made by two operations. Again, the unit of water is made by two operations like the unit of oxygen; but it differs from the unit of oxygen in this respect, that one of those operations is the same as that by which hydrogen is made, and the other is the same as that by which oxygen is made. That is to say, in the operation by which water was formed, you would hear two sounds, one different from the other, α, ξ.

The symbol of chlorine is $\alpha\chi^2$. Chlorine from this point of view, is to be conceived as made up of three operations. You are to hear χ, χ, and the α again. One of these operations is the same as that by which hydrogen is made, and the other is an operation peculiar to chlorine itself, namely, χ. Again: a unit of hydrochloric acid—a thousand cubic centimetres, in the condition of a perfect gas at a pressure of 760 millimetres—is to be conceived of as made by two operations, $\alpha\chi$.

To go one step further: let me refer you to this table:—

Nitrogen	$\alpha\nu^2$
Ammonia	$\alpha^3\nu$
Protoxide of Nitrogen	$\alpha\nu^2\xi$
Nitrous Acid	$\alpha\nu\xi^2$
Nitric Acid	$\alpha\nu\xi^3$
Phosphorus	$\alpha^3\phi^4$
Phosphide of Hydrogen	$\alpha^3\phi$
Hypophosphorus Acid	$\alpha^3\phi\xi^2$
Orthophosphoric Acid	$\alpha^3\phi\xi^4$
Terchloride of Phosphorus	$\alpha^3\phi\chi^3$
Pentachloride of Phosphorus	$\alpha^3\phi\chi^5$

Nitrogen is to be conceived of here as made of three operations, $\nu\nu$, and then α upon that. In the formation of the unit of ammonia three operations concur. One of them being one of the operation of nitrogen, ν, and the other two being the operation by which hydrogen is formed, α.

I must not enter into further details upon this subject, but I have little doubt that, with this explanation, you will readily appreciate the meaning of the symbols which are written up before you. You will see that, by following this process of taking the facts of the equations and turning them into the language of symbols, we arrive at a peculiar view as to the nature of matter, which view is embodied in those symbols.

Now, as to the nature of the view which is here indicated, for that, perhaps, will occur to most persons as the most important point to be considered. This view is the only result which I have placed before you in the first part of this method. It is the view as to the nature of matter itself. You will observe that, looking simply from the general point of view of the nature of matter, the point which it is most important for us to insist upon is the nature of the elemental bodies, because it is out of these elemental bodies that everything else is made, and into them all things are capable of being resolved. The view which we take of these bodies gives to us implicitly the view which we are to take of the composition of every other body whatever. To understand this it is only necessary to appreciate the view which is here given of the nature of the elements themselves, and everything else follows from that. We are led to the following singular results,—that, speaking generally, there are, perhaps, four—certainly at least three—fundamentally distinct classes of the elemental bodies.

First of all, there are elemental bodies, the units of which are made by one indivisible operation. These bodies are represented to us by mercury and hydrogen. To this class also probably belong such elements as zinc, cadmium, and tin; but we cannot speak with great confidence on that point.

Secondly, we have a class of double elements, formed by two similar operations; these are oxygen ξ^2, sulphur θ^2, selenium λ^2. Carbon we are not certain about; it belongs, in all probability, to the first or second class, we do not quite know which; but I have symbolized it as κ^2.

But we have another and a very large class—perhaps the largest of all the groups of the elements—and we may take the elements chlorine and nitrogen as representatives of it. Here is the symbol of the element chlorine, $\alpha\chi^2$; here is nitrogen, $\alpha\nu^2$; here is iodine, $\alpha\omega^2$; and so on. You will see that the symbols of these elements occupy a certain intermediate position between this group of elements, α, ι, ζ, etc., and that group of elements, ξ^2, θ^2, λ^2, etc. We have many compound substances which are in every way analogous to this group of elements—analogous as to their properties, analogous as to their symbols. Of this class we have a most interesting and striking example in the peroxide of hydrogen; it is symbolized here as $\alpha\xi^2$. You see the peroxide of hydrogen is really to be regarded as the combination of one unit of the element hydrogen with one unit of oxygen—which things really exist—just as the element chlorine may be regarded as a combination of the unit of hydrogen (α) with a substance which does not exist, and which I have symbolized as χ^2. The unit of nitrogen is to be regarded as similarly composed ($\alpha\nu^2$). We may regard it as α combined with the unknown element ν.

There is one question which must occur to every one, the explanation of which is of fundamental importance to the comprehension of this system. You may ask me, "What do you mean by these symbols—by calling chlorine $\alpha\chi^2$; nitrogen $\alpha\nu^2$; oxygen ξ^2? Do you mean that there are certain portions of matter, really existing, capable of being brought to the lecture-room—theoretically, at any rate—and shown upon the lecture-table: portions of matter which are represented by α and χ, α and ν, and so on? Do you mean this? or do you mean that these things are the creation of your imagination—that they are fictions—illusions? We like," perhaps you may say to me, "we like Dalton a great deal better than we do you; for Dalton, at any rate, dwelt with realities, or possible realities. He, at any rate, showed us the matter of which all substances are made. He brought the elemental bodies into the lecture-room in bottles, and he showed us there the elements out of which matter is made. Are you going to do that? Do you mean to show us α, ξ, χ, in the lecture-room? Again, Dalton dealt with realities through these atoms. Although, certainly, we have never seen them, yet, nevertheless, we most perfectly believe them to exist. There are such things as atoms, although we have never seen them. Dalton brought the elements to the lecture-table; and if he did not actually show us the atoms, you will find pictures of them at the end of his book; he made little bits of wood, which were excessively like atoms although they were wood. But you don't even do this for us." Well, this is rather a perplexing question; for if you ask me if these things really exist—whether they are things capable of being brought to the lecture-table and placed before us—in answer to such an inquiry I say, in the first place, that they do not necessarily exist. Then, again, you ask me this: "Do you say that they are imaginary things, that they are creations of your fancy? Because, if so, we don't trouble ourselves much about your fancies. They are not worth thinking about." I say, no, they are not fancies of mine; I never made them, I only found them. Then you answer: "All things are either imaginary or real; which are these?" Well, I reply, these things are *ideal* things. Well, then, my friend says I am getting beyond him when I say these are ideal, for he does not understand what ideal things are: all things are either imaginary or real. Yes; but I say there is a point which you have overlooked. Either all things exist according to the laws of nature which make it possible for them to exist, or there are insuperable barriers in the laws of nature to their existence. But though we may not know whether certain things exist or do not exist, yet we may reason about these things as if they were real things. A thing may not exist at all, but yet it may serve to us all the purposes of a real thing. That is what I mean by an ideal thing. It is a thing which may exist or may not exist, we do not know which, but which satisfies all the conditions of reality.

I shall venture, at the risk of delaying you a little longer, to give you an illustration on this point, which was suggested to me by some remarks and illustrations of Professor Stokes, with whom I have had the, to me, incomparable advantage of discussing and considering several of these difficult and abstruse questions. My illustration is simply his illustration a little modified for you. I am going to make a general assertion. I will draw a conic section—a curve on the board, and I am going to say that every straight line cuts every conic section in two points. That, you see, is somewhat analogous to my statement, that the unit of every chemical substance is composed of an integral number of prime factors, and is to be regarded as made up of an integral number of these bits of matter which I call symbol weights. There are the two corresponding assertions. But you say, "Do you mean that every straight line really cuts the conic section in two points?" I say, no, I never said that it *really* cut it at all. I said it *cut* it. Then you say, "Do you mean that it cuts in imagination?" I say, no, I do not say this. I do not know whether the line cuts it in reality or in the abstract. I do not know, speaking generally, whether the points at which a straight line cuts a conic section are real or imaginary. They are one or the other. You see that is a perfectly general mathematical truth and principle. Nothing is easier than to prove any proposition; and I may go on to say, that in the case of a straight line, of course, we can go farther: we can investigate the nature of these points; we can determine the nature of these points. But in chemistry we come to a bar. We cannot go on. We have not yet got the data to prove whether these prime factors, these units of weights, are real things or imaginary. They are undoubtedly one or the other, but we cannot tell which. There are facts here which satisfy all the analytical conditions of the facts, whether the matter is real or imaginary. There are symbols of facts, which satisfy the analytical conditions supplied to us by the equations of chemistry, and as such we are bound to accept them. We cannot do otherwise. It is impossible for us not to accept the conclusion.

We cannot, however, entirely dismiss from our consideration the alternative that these portions of matter— α, χ, ξ, ν, and ω, may be real. I *mean* a real thing when I say "a real thing." I mean something which may be brought to the lecture-table and put there, really or theoretically. We cannot close our eyes to the alternative; and there really are, though not at all derived from this method itself, but derived from other considerations, certain real reasons which would lead us to suspect that chemical substances are really composed of a primative system of elemental bodies, analogous in their general nature to our present elements, some of which we possess, but of which we possess only a few. I will take the case of the peroxide of hydrogen. I will throw overboard oxygen and a great class of certain oxygenated combinations, and I will suppose for the moment that I have these combinations—hydrogen, water, peroxide of hydrogen, and certain other substances which I could specify. If I were to apply my method to finding the symbol of peroxide of hydrogen, not regarding the oxygen at all, the symbol at which we arrive for peroxide of hydrogen is $\alpha\xi^2$. Thus the same question would arise in that case about peroxide of hydrogen as now arises about chlorine. In peroxide of hydrogen we really have succeeded in separating the elements which it contains, and this fact leads us to the suspicion that some of these bodies which we speak of as elements may in fact be compounds. In short we are led, through our method, to a certain physical hypothesis, of whatever value that hypothesis may be, as to the origin and causes of chemical phenomena.

Now, what I am going to suggest is of course put before you with reservation, but we may conceive that, either in remote time, or in remote space, there either did exist formerly, or there do exist now, certain simpler forms of matter than we find upon the surface of our globe—α, χ, ξ, ν, and so on—in short, these symbols of chemical operations. I say we may at least conceive of, or imagine the existence, either in time or in space, of these simpler forms of existence, of which we have some records remaining to us. Here they are—hydrogen and mercury—two things. We may consider that in remote ages the temperature of matter was much higher than it is now, and that these other things existed then in the state of perfect gases—separate existences—uncombined at any rate. This is the farthest barrier to which we can reach. There may be something farther, but if so, we can have no suspicion of it from the facts of the science. We may, then, conceive that the temperature begins to fall; these things begin to combine with one another. They enter into new forms of combination, appropriate to the circumstances in which they are placed. The result is the formation of new combinations. We may suppose that at this time water ($\alpha\xi$) hydrochloric acid ($\alpha\chi$), and many other bodies began to exist. Now, we may further consider that as the temperature went on falling, certain forms of matter became more permanent and more stable, to the exclusion of others. We have evidence on the surface of our globe itself, of the permanence of certain forms of matter to the exclusion of others. We may conceive of this process of the lowering of the temperature going on, so that these substances, $\alpha\chi^2$ and $\alpha\nu^2$, when they were once formed could never be decomposed—in fact that the resolution of these bodies into their component elements could never occur again. You then have something of our present system of things. You might yet imagine that it would be possible, on looking carefully at chemical equations, and minutely studying them, to recover from the equations the record of the truths which were buried and preserved in the equations; and some analyst might come and say, "These equations are *only* consistent with this hypothesis, that chlorine is composed of α and χ^2," or, at least, it might be said that the equations *are* consistent with that hypothesis, for I do not want to go farther than that. In short, we can conceive of such a state of things. Now, this is not really and purely an imagination, for when we look upon the surface of our globe, as I said before, we have evidence of similar changes in nature. We talk of the elemental bodies as though they were existing things; but where are they? We have oxygen, nitrogen, sulphur, certain metals, and certain bodies which we could specify, but what has become of the others? Where is hydrogen?. Where is chlorine? Above all, where is fluorine? Where are these things? Why, they are at any rate locked up in combination, in such a way that it is only within the last hundred years that the art of the chemist has revealed them to mankind. Now, if in our globe there had been more hydrogen—if there had been an excess of hydrogen present in the matter from which our globe was made—and if we suppose it to be true that the gases condense in the solid matter of our globe, we cannot doubt that the whole of the free oxygen would have been carried away from our planet, and that we should have had simply oxygen stored up in the form of water. We should have had water, but no oxygen at all; all the hydrogen would have combined with it and carried it all away.

When we look at some of the facts which have been revealed to us, by the extraordinary analyses which have been made of the matter of distant worlds and nebulæ, by means of the spectroscope, it does not seem quite incredible to me that there may even be evidence, some day, of the independent existence of such things as these, χ and ν. We know that Dr. Miller and Mr. Huggins saw a most wonderful hydrogen combustion—at least, what they imagined to be a hydrogen combustion—taking place in a variable star. Now, for aught we know to the contrary, this hydrogen combustion might be merely hydrogen combining with unknown elements, and carrying them all away in the form of chlorine, nitrogen, and the like. One of the nebulæ examined by Dr. Miller and Mr. Huggins afforded them the spectrum of an ignited gas, and in the spectrum of the nebula they saw one of the lines of nitrogen alone. Now, this suggests that this line might have been produced by one of the elements of nitrogen, before it had combined with another substance to form nitrogen. That might have been the element, ν. I am only suggesting that; but I say that if we follow up the subject we may have, one day revealed to us, independent evidence of the existence of these elements.

Let me, in conclusion, make one or two observations upon a point which, of course, must occur to every chemist who has studied this method. If we had taken, not α as the symbol of hydrogen, but had started with a different hypothesis, namely that the symbol of hydrogen was α^2, we should, of course, have arrived at a different symbolic system, that would have been analogous in its form to our present symbolic system—that is to say, you might have given to it an interpretation analogous to that system. We should have had hydrogen as α^2; water $\alpha^2\xi$, and so on. In fact, we should have been led to develop a system different from that which I have brought before you. You may with reason ask me, "Why do you prefer one of these systems to the other; or do you prefer it; or what view do you take of that question?" Let me say, in the first place, that my object has been, hitherto at least, not to give you a very definite answer to this question. For I have not yet placed before you and others, the ideas upon which a judgment can properly be formed on the question; but it is certainly true, in a certain sense, that there is more than one answer to the chemical problem, and that this system as thus developed, leads to another solution of the question. It gives you another answer to your inquiry. But further than this, there may be other answers still, although, perhaps, these are the only two answers necessary in considering the chemical problem; and this point which I wish to bring before you is of a far more subtile nature than it has been suspected to be. It is a method which you cannot attempt by the modes of atomic symbolism. It may be regarded as an equation of which there are not only one root, but several roots. Some of these roots may be thrown away, but some may lead us to a real solution. Now, I am not saying that one answer is the same in kind as the other answer, for I, with a natural preference, select the system α. I think there is something there, which is really of more importance and more necessary, in expressing the symbols than that which is given in the second system. I do not at all disregard that system. Indeed, I shall hereafter consider it, and endeavour to see, at any rate, what it means; but, I say, there is something in my system which is not in the second system—something in the system of α, which is not in the system of α^2. I cannot discuss this question with the hope of producing conviction in your minds, but I will just point out one fact. It is this—that you can pass from the system of α to the system of α^2 by a direct process of substitution. I mean, that if you say that here are two independent systems—the system of α, and the system of α^2—I say those systems are not entirely independent; for if you have constructed the system of α, you can make a substitution of α^2 for all. What that system would be, it is not necessary here to imagine. But having constructed this system of α^2, you cannot go back. It is not a logical consequence at all that, because you can take the square of the first system, therefore you can go back again. It will be absolutely impossible to pass at all from the latter system to the former. The one is derived primarily by substitution, and the other is not derived purely by substitution, but first by substitution, and then by reduction.

Discussion.

Dr. **Frankland**: I am sure, sir, that I only express the feelings of every one present when I say that I have listened to the lecture which Sir Benjamin Brodie has just given us with great interest and admiration. I cannot help thinking that the bringing forward of an entirely new method of viewing chemical phenomena such as has been brought before us to-night, must be fraught with great good to the science; but at the same time, I may be permitted, perhaps, having been alluded to in the earlier part of the lecture as a prominent advocate of what might be termed the opposite system of representing chemical facts, to protest at the outset, in the most emphatic manner, against the view which Sir Benjamin Brodie appears to have of such representations. I am not going to speak on behalf of other chemists who employ those more concrete modes of chemical representation. On my own behalf, however, in repudiation of the notion that I regard such representations as these graphic or glyptic formulæ, or even symbolic formulæ by letters only, in the sense of representations of the constitution of those portions of matter called atoms, or, as representations of the position of these atoms in the compound; perhaps I cannot do better than state, simply and at once, that I neither believe in atoms themselves, nor do I believe in the existence of centres of force, so that I do not think I can be fairly charged with this very crude notion which would otherwise attach to me with regard to the representation of such chemical compounds. Now, sir, many people, I believe, have been much dissatisfied of late with chemical formulæ in one respect, and I confess that I am one of the most dissatisfied. This note of dissatisfaction was, I believe, first expressed by Mr. Waterston. We do not express in our chemical formulæ, and in our chemical symbols, the idea of the *force* which has been involved in the operations expressed in those chemical compounds to which we apply the formulæ; and I think that one of the greatest advances which could possibly be made in the notation of chemical compounds, would be the introduction of this element. When, however, we leave statical formulæ—when we leave the mere representation of the atoms of compounds (if you will allow me figuratively, for a moment, to use the expression)—and when we go to the operations themselves by which those compounds are formed, I think we require then this expression of the forces involved, still more than we do in the statical formulæ that have hitherto been employed by chemists. Now, it appears to me, that we seek in vain for this element in the new development which Sir Benjamin Brodie has so eloquently placed before us this evening. Again, I think that every chemical formula is of use chiefly, if not only, as a means for future discovery in nature. So far as it serves that purpose it is of use; if it does not serve that purpose it is useless. The more, therefore, that a chemical formula expresses of our knowledge of the body for which we put it, the more valuable, I apprehend, that formula is. Now, if we take two well-known chemical compounds—namely, nitric acid on the one hand, and sulphuric acid on the other hand—I believe that if there is anything that we do know with certainty regarding these two acids, it is this: that in the case of nitric acid the hydrogen present in that compound can be taken out of it in one piece only, whilst in the sulphuric acid you can take out the hydrogen in two pieces. Now, when I look at the formula of nitric acid $\alpha\nu\xi^3$, and of sulphuric acid $\alpha\theta\xi^4$, I find in both these formulæ the same expression for the hydrogen; so that, I say, there is not contained in that formula the same amount of information, and of the most essential information, with regard to these two acids, that we possess in the present formula, differ as they may amongst different chemists, and lamentably they do so differ; still, by almost every chemist those two acids are expressed by formulæ representing this peculiarity of the hydrogen in those two compounds. These new formulæ, I say, do not express that idea, do not give us that information. I certainly do not imagine that any evil is likely to arise from such symbolical representations as have been hitherto used, even those of the very crudest kind which have been so strongly censured by Sir Benjamin Brodie; and, further, I do not think that science would ever suffer from the legitimate use of hypothesis. In fact, I cannot conceive of the future progress of science without such use of hypothesis: and I must say that it is to me a great recommendation for the new notation which has just been placed before us, that it involves a very fair amount of such hypothesis, which, I hope, will be capable of being used for the advance of the science, and for the benefit of its representations.

Professor **Clerk Maxwell** said he confessed that when he came into the room his feelings received a wholesome shock from two of the statements in the diagrams—first, that space was a chemical substance, and second, that hydrogen and mercury were operations. He now, however, understood what was meant. The present seemed to be an endeavour to cause the symbols of chemical substances to act in the formulæ according to their own laws. The formulæ at present used were made to express many valuable proper ties of chemical substances, just as a great many formulæ were employed to represent the syllogism in logic, which required a logical mind to form them, to understand them, and to reason upon them. The only successful attempt to introduce a new system in the logical representation was that of Mr. Boole, who accomplished it by the metaphysical and mathematical conception that x^2 was equal to x. In Sir Benjamin Brodie's system a did not mean exactly "hydrogen," but "make hydrogen;" that is, take the cubic centimetre of space, and put hydrogen into it of the proper pressure and temperature. But if they were to compress into that space another volume of hydrogen, that would not be a^2, because it would increase the pressure to double what it was before. If it were possible to get a^2, they would require to combine two volumes together by a process unknown to chemists, keeping the pressure and temperature as before. There was, in this respect, no doubt, an idea which differed from the mere collocation of symbols. The unit of ponderable matter described in the system was one which had been derived by chemists from chemical considerations alone. It had also been advocated by physicists from considerations derived from the theory of heat. In order to decide with certainty on the truth or falsehood of the atomic theory, it would be necessary to consider it from a dynamical point of view. He meant that kind of dynamics treated of in books on mechanics. It was worth while to direct the attention of chemists to the fact that a belief in atoms conducted necessarily to exactly the same definition as was given there—namely, that for every kind of substance the number of atoms, or molecules, in the gaseous state, occupying the space of a litre, at a temperature of 0 degrees, and of a pressure of 760 millimetres, must necessarily be the same. That was a consequence which could be deduced from purely dynamical considerations on the supposition advocated by Professor Clausius and others, that gases consist of molecules floating about in all directions, and producing pressure by their impact. That theory was now under probation among chemists, physicists, and others. The next step was one which might be far off—the finding of the number of these molecules. That number was a fixed one, and when it could be arrived at, we should have another unit of ponderable matter—that of a fixed molecule.

Professor Stokes (on being invited by the President to join in the discussion) said he had very little to add to what had been said; but referring to the way in which the symbols of some of the elements were arrived at, he might say they were based upon the known laws of combination by volume. The chief feature which struck him in the system of Sir Benjamin Brodie was, that it allowed them to express the composition of bodies by a method which took in all their existing knowledge, and did not assume anything besides. Of course the mode of expression was liable to change with an increase of knowledge; but taking their knowledge at a fixed point, such as it was at the present day, the method expressed everything that was known without superfluous hypotheses. The question of binoxide of nitrogen was a very important one; for if the known vapour density of that substance was to be admitted, it would seem to resign the question in favour of Laurent's system. On the other hand, if they agreed to pass over that anomaly for the present—and all chemists would admit that there was an apparent anomaly about it—then they were led to Sir Benjamin Brodie's system.

Mr. Wanklyn said the remarks of Professor Stokes had suggested what probably would occur to every one in the room—that the new method was a one-volume system. The well-known system of Gerhardt was a two-volume system.

Dr. Odling: The pleasure with which I have heard Sir Benjamin Brodie's lecture is, I am afraid, almost counterbalanced by the shock which my feelings received on hearing from Dr. Frankland that he questioned the positive existence of atoms. If Dr. Frankland's opinion on that subject was what he has stated, he has grossly deceived the chemical public. (Laughter.) The Chairman has said quietly aside to me that, after all, Dr. Frankland never really believed in atoms, or he would not have ventured to take such liberties with them. We have been led to believe that not only have we atoms, but that these atoms possess imaginary prongs, and that there is an imaginary clasping between them by means of these imaginary prongs, in a sort of hermaphroditism which it is scarcely possible to refer to. It behoves chemists to give their attention to this matter, as it affects their fundamental notions of chemical constitution and chemical change. After all, the system of symbols is a method of expression, and its value must depend upon its usefulness, upon the accuracy with which it expresses, and the facility with which it can be used. The accuracy with which Sir Benjamin's system can express, has been brought out in the part of his paper already published; but we wait for information on the facility with which the method can be used, and the advantages attending upon its use. It appears to me to possess one prominent merit, and that is expressed by the author in his paper—that the expressions are brought into immediate relations with the facts themselves. The present method of chemical expression, really, is not based directly upon the facts but upon the facts through the intervention of atomic theory. There is nothing of this kind in the method which the lecturer has introduced to the Society. No doubt the expression bears a relation directly to the fact, be the theory what it may. In the ordinary use of our present symbolic language, there are some chemists who, differing from Dr. Frankland, do believe in atoms, but who, not differing from Dr. Frankland, bring the idea of atoms prominently forward. On the other hand, there are some who, like myself, do not believe in atoms, and who keep the idea of atoms in the background as much as possible. But whether we do or do not believe in atoms, it still remains true that our notation is based upon the atomic theory, and without the atomic theory our language has no meaning whatever. One of the advantages of the new method is, that it is not inconsistent, by any means, with the atomic theory; but it is not based upon it. Another point of view from which the system commends itself even more strongly to our attention, is that which has been adverted to by Mr. Wanklyn, and which it does not require anybody to point out—namely, that it is a one-volume system, while the method which has been hitherto in use is a two-volume system. Laurent, however, has also introduced a one-volume system; but in that of the present author there is this additional feature: that it is the only mode introduced to chemists by which the volumes of substances can be represented by integral numbers without fractions. In Laurent's system there are fractions. It seems a thing altogether ridiculous that, under any system, we should adopt, as a unit of chemical substance, that which consists of two units, and which we are obliged to express in every way as consisting of two units. The new system is the first in which all prime factors can be written by an integral number. Another point of interest is the dissipation of that extraordinary law of even numbers which was brought into notice by Laurent and Gerhardt. Why that law should exist upon the atomic hypothesis, which is a dualistic hypothesis—the hypothesis which also exists in the expressions based on Laurent's one-volume system—is truly inconceivable; but in the mode of expression introduced by Sir Benjamin Brodie, this disappears altogether, and we get, at any rate, an entire series of compounds formed by the simple increment of atoms, one upon another, and without any of the objections which the ordinary formulæ present. Dr. Frankland has adduced, as a recommendation to this method, that it really introduces a great deal of hypothesis. There is no doubt that the whole system, as compared with the system of a^2, is based upon an hypothesis; but with the exception of that hypothesis, I do not think that there is anything hypothetical in the whole system. Admit, for one instant, the not improbable hypothesis that the unit of weight of hydrogen is an indivisible quantity, and all the remaining portion follows as a matter of course. There remains only the question whether the consequences, which the adoption of such an hypothesis leads to, are of such a character as to confirm the hypothesis, and, in fact, to demonstrate its truth. On that point I must say that I feel the difficulty which has been suggested by Dr. Frankland respecting the bodies which chemically behave in a different manner, and which are distributed in a different way, although, judging from their mere formulæ, it would be supposed that they should be distributed in an identical way. We have no means of separating, in our minds, that hydrogen which is distributable from that which is not. Altogether, I view the paper as of very great use to chemists, as calling upon them to consider the ground upon which their present opinions are based, and as shattering to the ground a great many of the superstructures which have been raised upon the old theory. The paper is of the highest importance and the greatest interest. I feel, as many must have felt upon former occasions, that a blow has been given to one's long-cherished convictions. But, at the same time, I am not at the present moment inclined to abandon them altogether. I look upon myself as vanquished for the moment, but I am not altogether disinclined to renew the combat, when further knowledge shall give me the means of doing so.

Mr. **Brayley** said that it appeared that one of the most striking and important elements of the subject which Sir Benjamin Brodie had placed before the Society, had not been adverted to by any of the gentlemen who had joined in the discussion. That was, the probability which it shadowed forth of discovering the compound nature of some of our present elements by a kind of chemical calculus. Professor Stokes had characterised the new method as embodying the representation of all we knew, but it appeared to add to this a hypothetical shadowing forth of what we might hope to know hereafter. It would be acceptable to chemists if the author would have the goodness to explain the manner in which he arrived, by his method, at the conclusion that whatever was represented by α (whether hydrogen or any other substance) was contained in all those haloid elements to which the sign of α was attached, such as chlorine, iodine, and bromine.

Mr. **Foster** said he thought the point which must strike chemists, at first sight at any rate, as the most interesting result of Sir Benjamin Brodie's method, was that it enabled them to arrive at the conclusion that some elements were, in point of fact, compounds. This, however, was by no means the first time it had occurred in the history of the science that chemists had arrived, by pure reasoning, at the conclusion that some substances, whose elements they did not know, were compounds. For instance, before it was known that the alkalies and the alkaline earths could be separated into oxygen and a metal, the majority of chemists were pretty well convinced that they were compound substances. And with regard to chlorine itself, that substance was, at its very discovery, viewed in a manner which was analogous to, if not, in point of fact, identical with, the view which was indicated by Sir Benjamin Brodie's notation. Hydrogen, hydrochloric acid, and chlorine were regarded in early times as bodies which formed a series with each other, hydrochloric acid being exactly half-way between hydrogen and chlorine. One point which had been alluded to, as well by Dr. Frankland as by Dr. Odling, was that the symbols exhibited in the diagram did not, in all cases, express quite as much, from some points of view, as the ordinary chemical formulæ. For instance, the formulæ of sulphuric acid and of nitric acid did not show that the sulphuric acid was what was commonly called bibasic, and nitric acid monobasic. That, he thought, was hardly a fair criticism upon the formulæ. For sulphuric acid the symbol was $\alpha\theta\xi^4$; for nitric acid the symbol was $\alpha\nu\xi^3$. But although the symbol representing hydrogen occurred merely once in each formula, still, having regard to the other letters, these tell us that the hydrogen is distributable in one case and not in the other. Take again the similar cases of water and hydrochloric acid. The first was represented by $\alpha\xi$, and the other by $\alpha\chi$. One of the properties of the symbol χ was to render the α with which it was combined undistributable, whereas the ξ combined with the hydrogen rendered the hydrogen distributable; so that although α occurred once only in the formulæ of water and hydrochloric acid, the other letters showed that its properties varied. They should, therefore, judge of the formula, not by one of its signs alone, but by the varied meaning due to the collocation of symbols.

Dr. **Williamson** (Chairman): I cannot refrain from expressing on my own behalf, what I am sure must have been felt by all present—the strong sense of the obligation under which we are placed to our eminent colleague, for the most laborious and most important work which he has been carrying on for many years, though it is only now becoming known to chemists. It is a peculiarly difficult thing to dissociate oneself from the prevailing ideas on such a subject as has been put before the Society; and yet such dissociation is essential to the working out of any truly new conception, and especially any new mode of expression. The novelties of expression which Professor Maxwell spoke of as having been a shock to him, are in themselves the essential condition of the working out of the new system of notation. One is, perhaps, pained on first hearing that 1 is equal to zero. Nor are we accustomed to understand an operation performed merely upon space. I must confess that although I have given considerable time and attention to the paper, I do not feel that I am in a condition to fully appreciate all the expressions used in that part of the system already published. There are some things which I feel hardly able to accept on the present basis; but, at the same time, I feel that until one can understand in plain English and in ordinary words the meaning of those operations and things denoted, it will be exceedingly presumptuous to doubt the correctness of results which have *primâ facie* evidence of great consistency. Every chemist must be struck with the unity and consistency of the new method; but those qualities cannot be attributed to the present system of notation. I am quite convinced that whatever modifications Sir Benjamin Brodie's system may undergo at the hands of its author, its introduction will inaugurate an exceedingly important era in chemical language and notation. I am sure the Society will join with me in thanking the author most cordially for the great intellectual feat which he has performed in working out this subject, and in hoping that before long he may accomplish some further steps in his great work.

The Lecturer's Reply.

Sir **Benjamin Brodie**: I do not know that there really remains very much for me to say upon this matter. With many of the remarks that have been made, both by Professor Frankland and Dr. Odling, I cannot but agree. I think, myself, that the object of a method is not simply to give us statical formulæ, but that we must also consider the dynamics of the science. I mean by "statical formulæ," that we are not merely to consider what matter is, but that we are to consider the laws also, by which matter changes; and that is a point upon which I hope to throw some light at a future time, in the second part of the paper. It is then that the question will naturally arise as to the way in which the kinds of facts, which it has been attempted to express by the theories of atomicity, will appear in this method. You must not suppose, because I have not entered upon these subjects, that I have ignored them; I only postpone the consideration of them. With regard to the other point, about the relative merits of this mode of statement and the one ordinarily in use, I think that some of the remarks of Dr. Frankland, and my friend Dr. Odling too, are based simply upon a misconception. Dr. Frankland seems to imagine, in the case of such symbols as those of nitric acid $\alpha\nu\xi^3$, and of sulphuric acid $\alpha\theta\xi^4$, that the important and fundamental distinction which is assumed in our present system to consist in the different number of atoms of replaceable hydrogen which these substances respectively contain, is altogether obliterated and lost sight of. But this is not so. By simple inspection of the symbols, you can ascertain precisely, as in our present notation, the changes of this order of which chemical substances are susceptible. But, as Professor Foster justly observes, you must take into account the whole symbol, and not a bit of it only. If you take into account the fact that the matter of all known chemical substances is identical with the matter of the elementary bodies, then there is nothing to be added. To one who is familiarised with the use of these expressions (when this point is properly regarded), it is at once apparent, that, whereas we can perform two of the operations, for example, symbolised in χ, and two only of those operations, upon the symbol $\alpha\theta\xi^4$, we can perform one, and one only, of those operations upon the symbol $\alpha\nu\xi^3$. These important questions, however, cannot be thus briefly discussed, and I must defer their consideration to other opportunities.

ROYAL INSTITUTION.

*On the Chemistry of the Primeval Earth**, *by* T. Sterry Hunt, M.A., F.R.S

The subject of my lecture this evening, as has been announced, is the Chemistry of the Primeval Earth. The natural history of our planet, to which we give the name of geology, is, necessarily, a very complex science, including, as it does, the concrete sciences of mineralogy, of botany, and zoology, and the abstract sciences of chemistry and physics. These latter sustain a necessary and very important relation to the whole process of development of our earth from its earliest ages, and we find that the same chemical laws which have presided over its changes apply also to those of extra-terrestrial matter. Recent investigations show the presence in the sun, and even in the fixed stars—suns of other systems—the same chemical elements as in our own planet. The spectroscope, that marvellous instrument, has, in the hands of modern investigators, thrown new light upon the composition of the farthest bodies of the universe, and has made clear many points which the telescope was impotent to resolve. The results of extra-terrestrial spectroscopic research have lately been set forth in an admirable manner by one of its most successful students, Mr. Huggins. We see by its aid matter in all its stages, and trace the process of condensation and the formation of worlds. It is long since Herschel, the first of his illustrious name, conceived the nebulæ, which his telescope could not resolve, to be the uncondensed matter from which worlds are made. Subsequent astronomers, with more powerful glasses, have been able to show that many of these nebulæ are really groups of stars, and thus a doubt was thrown over the existence in space of nebulous luminous matter: but the spectroscope has now placed the matter beyond doubt. We thus find in the heavens planets, bodies like our earth, shining only by reflected light; suns, self-luminous, radiating light from solid matter; and, moreover, true nebulæ, or masses of luminous gaseous matter. These three forms represent three distinct phases in the condensation of the primeval matter, from which our own and other planetary systems have been formed.

This nebulous matter is conceived to be so intensely heated as to be in the state of true gas or vapour, and, for this reason, feebly luminous when compared with the sun. It would be out of place, on the present occasion, to discuss the detailed results of spectroscopic investigation, or the beautiful and ingenious methods by which modern science has shown the existence in the sun, and in many other luminous bodies in space, of the same chemical elements that are met with in our earth, and even in our own bodies; realising, in a most literal manner, the genial intuition of the poet, who

> "Sees alike in stars and flowers a part
> Of the self-same universal being
> That is throbbing in his mind and heart."

Calculations based on the amount of light and heat radiated from the sun show that the temperature which reigns at its surface is so great that we can hardly form an adequate idea of it. Of the chemical relations of such intensely heated matter modern chemistry has made known to us some curious facts, which help to throw light on the constitution and luminosity of the sun. Heat, under ordinary conditions, is favourable to chemical combination, but a higher temperature reverses all affinities. Thus, the so-called noble metals, gold, silver, mercury, &c., unite with oxygen and other elements; but these compounds are decomposed by heat, and the pure metals are regenerated. A similar reaction was many years since shown by Mr. Grove with regard to water, whose elements—oxygen and hydrogen—when mingled and kindled by flame, or by the electric spark, unite to form water, which, however, at a much higher temperature, is again resolved into its component gases. Hence, if we had these two gases existing in admixture at a very high temperature, cold would actually effect their combination precisely as heat would do if the mixed gases were at the ordinary temperature, and literally it would be found that "frost performs the effect of fire." The recent researches of Henry Ste.-Claire Deville and others go far to show that this breaking up of compounds, or dissociation of elements by intense heat, is a principle of universal application; so that we may suppose that all the elements, which make up the sun or our planet, would, when so intensely heated as to be in that gaseous condition which all matter is capable of assuming, be uncombined—that is to say, would exist together in the condition of what we call chemical elements, whose further dissociation in stellar or nebulous masses may even give us evidence of matter still more elemental than that revealed by the experiments of the laboratory, where we can only conjecture the compound nature of many of the so-called elementary substances.

The sun, then, is to be conceived as an immense mass of intensely heated gaseous and dissociated matter, so condensed, however, that, notwithstanding its excessive temperature, it has a specific gravity not much below that of water, probably offering a condition analogous to that which Cagniard de la Tour observed for volatile bodies when submitted to great pressure at temperatures much above their boiling point. The radiation of heat going on from the surface of such an intensely heated mass of uncombined gases, will produce a superficial cooling, which will permit the combination of certain elements and the production of solid or liquid particles, which, suspended in the still dissociated vapours, become intensely luminous and form the solar photosphere. The condensed particles, carried down into the intensely heated mass, again meet with a heat of dissociation, so that the process of combination at the surface is incessantly renewed, while the heat of the sun may be supposed to be maintained by the slow condensation of its mass; a diminution by $\frac{1}{1000}$th of its present diameter being sufficient, according to Helmholtz, to maintain the present supply of heat for 21,000 years.

This hypothesis of the nature of the sun and of the luminous process going on at its surface, is the one lately put forward by Faye, and, although it has met with opposition, appears to be the one which accords best with our present knowledge of the chemical and physical conditions of matter, such as we must suppose it to exist in the condensing gaseous mass, which, according to the nebular hypothesis, should form the centre of our solar system. Taking this, as we have already done, for granted, it matters little whether we imagine the different planets to have been successively detached as rings during the rotation of the primal mass, as is generally conceived, or whether we admit with Chacornac a process of aggregation, or concretion, operating within the primal nebular mass, resulting in the production of sun and planets. In either case we come to the conclusion that our

---

* Reported specially for this paper, and revised by the author.

earth must at one time have been in an intensely heated gaseous condition, such as the sun now presents, self-luminous, and with a process of condensation going on at first at the surface only, until by cooling it must have reached the point where the gaseous centre was exchanged for one of combined and liquefied matter.

Here commences the chemistry of the earth, to the discussion of which the foregoing considerations have been only preliminary. So long as the gaseous condition of the earth lasted, we may suppose the whole mass to have been homogeneous; but when the temperature became so reduced that the existence of chemical compounds at the centre became possible, those which were most stable at the elevated temperature then prevailing, would be first formed. Thus, for example, while compounds of oxygen with mercury, or even with hydrogen, could not exist, oxides of silicon, aluminum, calcium, magnesium, and iron might be formed and condense in a liquid form at the centre of the globe. By progressive cooling, still other elements would be removed from the gaseous mass, which would now become the atmosphere of the non-gaseous nucleus. We may suppose an arrangement of the condensed matters at the centre according to their respective specific gravities, and thus the fact that the density of the earth as a whole is about twice the mean density of the matters which form its solid surface. Metallic or metalloidal compounds of elements grouped differently from any compounds known to us, and far more dense, may exist in the centre of the earth.

The process of combination and cooling having gone on, until those elements which are not volatile in the heat of our ordinary furnaces, were condensed into a liquid form, we may here inquire what would be the result, upon the mass, of a further reduction of temperature. It is generally assumed that in the cooling of a liquid globe of mineral matter, congelation would commence at the surface, as in the case of water; but water offers an exception to most other liquids, inasmuch as it is denser in the liquid than in the solid form. Hence ice floats on water, and freezing water becomes covered with a layer of ice, which protects the liquid below. With most other matters, however, and notably with the various mineral and earthy compounds analogous to those which may be supposed to have formed the fiery-fluid earth, numerous and careful experiments show that the products of solidification are much denser than the liquid mass; so that solidification would have commenced at the centre, whose temperature would thus be the congealing point of these liquid compounds. The important researches of Hopkins and Fairbairn on the influence of pressure in augmenting the melting-point of such compounds as contract in solidifying, are to be considered in this connexion.

It is with the superficial portions of the fused mineral mass of the globe that we have now to do, since there is no good reason for supposing that the deeply-seated portions have intervened in any direct manner in the production of the rocks which form the superficial crust. This, at the time of its first solidification, presented probably an irregular, diversified surface, from the result of contraction of the congealing mass, which at last formed a liquid bath of no great depth, surrounding the solid nucleus. It is to the composition of this crust that we must now direct our attention, since therein would be found all the elements (with the exception of such as were still in the gaseous form) now met with in the known rocks of the earth. This crust is now everywhere buried beneath its own ruins, and we can only, from chemical considerations, attempt to reconstruct it. If we consider the conditions through which it has passed, and the chemical affinities which must have come into play, we shall see that they are just what would now result if the solid land, sea, and air were made to react upon each other under the influence of intense heat. To the chemist it is at once evident that from this would result the conversion of all carbonates, chlorides, and sulphates into silicates, and the separation of the carbon, chlorine, and sulphur in the form of acid gases, which, with nitrogen, watery vapour, and a probable excess of oxygen, would form the dense primeval atmosphere. The resulting fused mass would contain all the bases as silicates, and must have much resembled in composition certain furnace slags, or volcanic glasses. The atmosphere, charged with acid gases which surrounded this primitive rock, must have been of immense density. Under the pressure of such a high barometric column, condensation would take place at a temperature much above the present boiling-point of water, and the depressed portions of the half-cooled crust would be flooded with a highly heated solution of hydrochloric acid, whose action in decomposing the silicates is easily intelligible to the chemist. The formation of chlorides of the various bases, and the separation of silica, would go on until the affinities of the acid were satisfied, and there would be a separation of silica taking the form of quartz, and the production of a sea-water holding in solution, besides the chlorides of sodium, calcium, and magnesium, salts of aluminium and other metallic bases. The atmosphere being thus deprived of its volatile chlorine and sulphur compounds, would approximate to that of our own time, but differ in its greater amount of carbonic acid.

We next enter into the second phase in the action of the atmosphere upon the earth's crust. This, unlike the first, which was subaqueous, or operative only on the portion covered with the precipitated water, is sub-aerial, and consists in the decomposition of the exposed parts of the primitive crust under the influence of the carbonic acid and moisture of the air, which would convert the complex silicate of the crust into a silicate of alumina, or clay, while the separated lime, magnesia, and alkalies, being converted into carbonates, would be carried down into the sea in a state of solution. The first effect of these dissolved carbonates would be to precipitate the dissolved alumina and the heavy metals, after which would result a decomposition of the chloride of calcium of the sea-water, resulting in the production of carbonate of lime or limestone, and chloride of sodium or common salt. This process is one still going on at the earth's surface, slowly breaking down and destroying the hardest rocks, and, aided by mechanical processes, transforming them into clays; although the action, from the comparative rarity of carbonic acid in the atmosphere, is less energetic than in earlier times, when the abundance of this gas and a higher temperature, favoured the chemical decomposition of the rocks. But now, as then, every clod of clay formed from the decay of a crystalline rock corresponded to an equivalent of carbonic acid abstracted from the atmosphere, and equivalents of carbonate of lime and common salt formed from the chloride of calcium of the sea-water.

It is very instructive, in this connexion, to compare the composition of the waters of the modern ocean with that of the sea in ancient times, whose composition we learn from the fossil sea-waters which are still to be found in certain regions, imprisoned in the pores of the older stratified rocks. These are vastly richer in salts of lime and magnesia than those of the present sea, from which have been separated, by chemical processes, all the carbonate of lime of our limestones with the exception of that derived from the sub-aerial decay of calcareous silicates belonging to the primitive crust.

The gradual removal, in the form of carbonate of lime, of the carbonic acid from the primeval atmosphere, has been connected with great changes in the organic life of the globe. The air was doubtless at first unfit for the respiration of warm-blooded animals, and we find the higher forms of life coming gradually into existence as we approach the present period of a purer air. Calculations lead us to conclude that the amount of carbon thus removed in the form of carbonic acid has been so enormous, that we must suppose the earlier forms of air-breathing animals to have been peculiarly adapted to live in an atmosphere which would probably be too impure to support modern reptilian life. The agency of plants in purifying the primitive atmosphere was long since pointed out by Brongniart, and our great stores of fossil fuel have been derived from the decomposition, by the ancient vegetation, of the excess of carbonic acid of the early atmosphere, which through this agency was exchanged for oxygen gas. In this connexion the vegetation of former periods presents the curious phenomenon of plants, allied to those now growing beneath the tropics, formerly flourishing within the polar circles. Many ingenious hypotheses have been proposed to account for the warmer climate of earlier times, but are at best unsatisfactory, and it appears to me that the true solution of the problem may be found in the constitution of the early atmosphere, when considered in the light of Dr. Tyndall's beautiful researches on radiant heat. He has found that the presence of a few hundredths of carbonic acid gas in the atmosphere, while offering almost no obstacle to the passage of the solar rays, would suffice to prevent almost entirely the loss by radiation of obscure heat, so that the surface of the land beneath such an atmosphere would become like a vast orchard-house, in which the conditions of climate, necessary to a luxuriant vegetation, would be extended even to the polar regions. This peculiar condition of the early atmosphere cannot fail to have influenced in many other ways the processes going on at the earth's surface. To take a single example: one of the processes by which gypsum may be produced at the earth's surface involves the simultaneous production of carbonate of magnesia. This, being more soluble than the gypsum, is not always now found associated with it, but we have indirect evidence that it was formed, and subsequently carried away, in the case of many gypsum deposits whose thickness indicates a long continuance of the process, under conditions much more perfect and complete than we can attain under our present atmosphere. While studying this reaction I was led to inquire whether the carbonic acid of the earlier periods might not have favoured the formation of gypsum, and I found, by repeating the experiments in an artificial atmosphere impregnated with carbonic acid, that such was really the case. We may thence conclude that the peculiar composition of the primeval atmosphere, was the essential condition under which the great deposits of gypsum, generally associated with magnesian limestones, were formed.

The reactions of the atmosphere which we have considered, would have the effect of breaking down and disintegrating the surface of the primeval globe, covering it everywhere with beds of stratified rock of mechanical or of chemical origin. These would now so deeply cover the partially cooled surface that the amount of heat escaping from below is inconsiderable, although in earlier times it was very much greater, and the increase of temperature met with in descending into the earth must have been many times more rapid than now. The effect of this heat upon the buried sediments would be to soften them, producing new chemical reactions between their elements, and converting them into what are known as crystalline or metamorphic rocks, such as gneiss, greenstone, granite, &c. We are often told that granite is the primitive rock or substratum of the earth, but this is not only unproved, but extremely improbable. As I endeavoured to show in the early part of this lecture, the composition of this primitive rock, now everywhere hidden, must have been very much like that of a slag or lava, and there are excellent chemical reasons for maintaining that granite is in every case a rock of sedimentary origin—that is to say, it is made up of materials which are deposited from water like beds of modern sand and gravel, and includes in its composition quartz, which so far as we know, can only be generated by aqueous agencies, and at comparatively low temperatures.

The action of heat upon many buried sedimentary rocks, however, not only softens or melts them, but gives rise to a great disengagement of gases, such as carbonic and hydrochloric acids, and sulphur compounds, all results of the reaction of the elements of sedimentary rocks, heated in presence of the water which everywhere filled their pores. In the products thus generated we have a rational explanation of the chemical phenomena of volcanos, which are vents through which these fused rock and confined gases find their way to the surface of the earth. In some cases, as where there is no disengagement of gases, the fused or half-fused rocks solidify *in situ*, or in rents or fissures in the overlying strata, and constitute eruptive or plutonic rocks like granite and basalt.

This theory of volcanic phenomena was put forward in germ by Sir John F. W. Herschel thirty years since, and, as I have during the past few years endeavoured to show, it is the one most in accordance with what we know both of the chemistry and the physics of the earth. That all volcanic and plutonic phenomena have their seat in the deeply buried and softened zone of sedimentary deposits of the earth, and not in its primitive nucleus, accords with the conclusions already arrived at relative to the solidity of that nucleus; and also with the remarkable mathematical and astronomical deductions of the late Mr. Hopkins, of Cambridge, based upon the phenomena of precession and nutation; those of Archdeacon Pratt; and those of Professor Thompson on the theory of the tides; all of which lead to the same conclusion—namely, that the earth, if not solid to the centre, must have a crust several hundred miles in thickness, which would practically exclude it from any participation in the plutonic phenomena of the earth's surface, except such as would result from its high temperature communicated by conduction to the sedimentary strata reposing upon it.

The old question between the plutonists and the neptunists, which divided the scientific world in the last generation, was, in brief, this—whether fire or water had been the great agent in giving origin and form to the rocks of the earth's crust. While some maintained the direct igneous origin of such rocks as gneiss, mica-schist, and serpentine, and ascribed to fire the filling of metallic veins, others—the neptunian school—were disposed to shut their eyes to the evidences of igneous action on the earth, and even sought to derive all rocks from a primal aqueous magma. In the light of the exposition which I have laid before you this evening, we can, I think, render justice to both of these opposing schools. We have seen how actions dependent on water and acid solutions have operated on the primitive plutonic mass, and how the resulting aqueous sediments, when deeply buried, come again within the domain of fire, to be transformed into crystalline and so-called plutonic or volcanic rocks.

The scheme which I have endeavoured to put before you in the short time allotted, is, as I have endeavoured to show, in strict conformity with known chemical laws and the facts of physical and geological science. Did time permit, I would gladly have attempted to demonstrate at greater length its adaptation to the explanation of the origin of the various classes of rocks, of metallic veins and deposits, of mineral springs, and of gaseous exhalation. I shall not, however, have failed in my object, if, in the hour which we have spent together, I shall have succeeded in showing that chemistry is able to throw a great light upon the history of the formation of our globe, and to explain in a satisfactory manner some of the most difficult problems of geology; and I feel that there is a peculiar fitness in bringing such an exposition before the members of this Royal Institution, which has been for so many years devoted to the study of pure science, and whose glory it is, through the illustrious men who have filled, and those who now fill, its professorial chairs, to have contributed more than any other school in the world to the progress of modern chemistry and physics.

ACADEMY OF SCIENCES.

June 3, 1867.

(FROM OUR SPECIAL CORRESPONDENT.)

M. DEBRAY, aided by M. Wisnegg, described and set to work two apparatus for producing very elevated temperatures by means of common gas mixed with air. The first was that of M. Schlösing, modified by M. Wisnegg, the second that of M. Perrot.

If a certain number of Bunsen burners be united together so as to form one single jet of flame, without, however, complete incorporation, the heating power is most remarkable, provided a sufficiently energetic and swift draught is given to it. The form of the furnace must also be varied, and the draught regulated, according to circumstances.

With an apparatus burning 70 cubic feet per hour, under a pressure of two or three inches of water, and without any draught but that obtained by a sheet-iron pipe 6¼ feet high, M. Debray was able in fifteen minutes to melt 670 grammes (1·48 lb.) of silver. It only takes half an hour at most, when the operation is at full work, to melt and cast a kilogramme of copper into a bar. Lastly, M. Debray melted several specimens of grey and white iron; a pound of a sort of cast-iron which passes for being very difficult to melt, was run in thirty minutes; another piece weighing 1¼ lb. was melted in an hour or so. During the operation the crucible can be examined in the interior by the aid of a mirror, or a bucket of water, which can receive the metal in case of accident.

M. Chevreul announced the melancholy news of the death of our esteemed friend, M. Pelouze, in a touching letter from his son. He was equally excellent as a father, husband, and practical chemist.

M. Tresca read the third part of his memoir "*On the Flowing of Solid Bodies, especially Metals, through Apertures.*" Pressure exerted on any point of a substance is transmitted throughout the interior of the mass.

M. Hulot, director of the workshops of the manufactory of postage-stamps at the Paris Imperial Mint, made two communications. "*On Aluminium Bronze and Aluminium Soldering.*" The paper, and especially that gummed and dried, as used for postage-stamps, rapidly deteriorates tools even of the best tempered steel. The 300 perforators for piercing the postage-stamps are used up after a day's work, in a few hours their ends become blunted, and instead of piercing only crush the paper, the last holes made being considerably enlarged. M. Hulot replaces the steel by aluminium bronze at 10 per cent., and the new tool, striking 126,000 blows per day, or 180,000,000 holes, has worked for several months without need of repairs. Aluminium bronze does not unite freely with solder by the old process; but if we take equal quantities of zinc amalgam and common solder, aluminium bronze can be admirably soldered together by it. This solder becomes better, again, if it is alloyed with once or twice its weight of tin. Thus we have three excellent solders—1st, solder with half its weight of amalgam; 2nd, with a fourth; 3rd, with an eighth. This is an excellent discovery, as it places aluminium on a new footing as regards mechanical appliances, especially for bushes or bearings for machinery, as the metal is almost indestructible by friction.

The Academy then proceeded to the election of a member in the section of medicine and surgery. M. Nélaton was elected, the majority consisting of thirty-two votes, against twenty-six given to M. Laugier.

June 10.

M. Schönbein placed a sealed letter in the hands of the Academy, containing a description of an important discovery by M. Liebig.

M. Boussingault communicated a new mode of finding the quantities of lime in analyses. The process consists in precipitating the lime in the state of sulphate, which is decomposed either by a Bunsen gas blowpipe or by one of Schlösing's furnaces, the sulphuric acid being vaporised, and the lime remaining pure. In several experiments on the decomposition of earthy or metallic sulphates, M. Boussingault remarked frequent anomalies, the quantity of the base remaining often being less than it ought to be. This fact is not easy to account for.

M. Payen reproduced in part his communication made to the Society of Encouragement, on the fabrication of paper pulp from wood fibre, and on the transformation of ligneous matters into cellulose and glucose.

MM. de Luca and Ubaldine communicated a "*Note on the Reaction between Sulphurous Acid and Sulphuretted Hydrogen.*" The sulphur which is deposited by the reciprocal action of sulphurous and hydrosulphuric acid consists of two varieties of sulphur, one soluble and the other insoluble in bisulphide of carbon. The relative proportion of these two sulphurs depends upon the conditions under which the operation is made; the quantity of insoluble sulphur is increased when an excess of sulphurous acid is present. The reaction expressed by the formula

$$2\,HS + SO_2 = 2\,HO + 3\,S$$

has its analogy in the reaction between sulphuretted hydrogen and selenious acid

$$2\,HS + SeO_2 = 2\,HO + SeS_2,$$

with this difference—that the bisulphide of sulphur $SS_2 = 3S$, etc., is replaced by the bisulphide of selenium SeS_2.

M. de la Rive read the principal conclusions of a memoir "*On the Sources and Phenomena of Atmospheric Electricity,*" but there was nothing new in it.

June 17.

M. Becquerel placed before the eyes of the Academy several specimens of metals reduced and precipitated by capillary action. In order to answer the objection that these phenomena of reduction or precipitation might be attributed to the action of the alkalies of the split glass tube, he employed polished plates of rock crystal applied one against the other so as to leave only a very small interval, and produce coloured rings; he has thus obtained perfect reduction of several metal. The interval between the plates must be varied according to the different metals, and he has obtained by this means the reduction of such metals as cobalt, nickel, copper, gold, etc. For the reduction of gold, for example, the space between the plates must be less than that for copper. When the solution is dilute, there is no further reduction of metal, but a precipitation of oxide.

M. Leverrier communicated the observations made by M. Wolf on the crater of Linnæus in the moon, from May 10 to June 10. His observations confirm those made by M. Rospighi at Rome. and lead to the same conclusion—viz., that it is not proved that there has been any change in this crater for a century.

M. Dumas read, in the name of M. de la Rive, of Geneva, a note upon an apparatus for measuring the different degrees of transparency of the air. According to M. de la Rive, the great transparency of the air before rain is due to the presence, in the air, of a quantity of invisible vapour which renders transparent the numerous germs floating in the air, to whose presence light mists are attributed.

CHEMICAL SOCIETY.

Thursday, June 20, 1867.

Dr. Warren De la Rue, *F.R.S., President, in the Chair.*

On the minutes being read, Dr. Thudichum protested against the interruption of Mr. R. Davey's speech by the Chairman on the last occasion; upon which Dr. Williamson answered by saying that he merely called to order a gentleman who, instead of speaking on the subject of Sir Benjamin Brodie's paper, was addressing inquiries to Mr. Davey. After this little *contretemps*, and a few words by way of further explanation from Mr. J. Newlands, the minutes were duly confirmed. Mr. J. C. Brough was formally admitted a Fellow of the Society, and the name of Mr. Charles M. Tidy, F.R.C.S., was read for the first time.

Mr. W. H. Perkin read a paper "*On Some New Derivatives of the Hydride of Salicyl.*" The author referred to a previous communication in which he had stated that the hydride of salicyl partook of the properties both of an alcohol and an aldehyde, and, upon extending these experiments, he has succeeded in producing several new derivatives containing the alcohol radicals.

Hydride of Methyl-Salicyl was formed by the action of iodide of methyl upon salicylate of sodium, in sealed tubes heated to 135-140° C. It separates as a light yellow or nearly colourless oil on adding water to the contents of the tubes. Washed with dilute solution of hydrate of potassium and re-distilled, the product came over at 238°. Its formula was established by two combustions, which gave—

$$C_8H_8O_2=HC_7H_4(CH_3)O_2.$$

The hydride of methyl-salicyl is isomeric with the hydride of anisyl, but differs from it both in boiling point and odour. It is a true aldehyde, and combines with the bisulphites, the potassium, sodium, and ammonium compounds of which are described.

Hydride of methyl bromosalical was formed as a substitution product by the action of bromine upon the hydride of methyl-salicyl. It separates from a hot alcoholic solution in the form of flat prismatic crystals, which fuse at 113-114·5° C., and have the following composition—

$$C_8H_7BrO_2=HC_7H_3Br(CH_3)O_2.$$

The actions of ammonia and of nitric acid have been studied; the latter gave rise to the production of two bodies —viz., a dark-coloured oil, which is probably the *hydride of mehtyl-nitrosalicyl* and a pale yellow crystalline body, assumed to be *methyl-nitrosalicylic acid.*

Hydride of ethyl-salicyl was formed in a manner similar to the first of this series. It is a nearly colourless, highly refractive oil, boiling at 247-249° C. Its composition is—

$$C_9H_{10}O_2=HC_7H_4(C_2H_5)O_2.$$

It possesses the properties of an aldehyde, and combines with the alkaline bisulphites.

The hydride of ethyl-bromosalicyl was produced by the action of bromine upon the preceding compound. The crystals fuse at 67-68° C., and contain $C_9H_9BrO_2$.

A new base *hydro-ethyl salicylamide*, $C_{27}H_{30}N_2O_3$, was formed by the action of alcoholic ammonia upon the hydride of ethyl-salicyl, according to the following equation :—

$$3C_9H_{10}O_2+{}_2H_3N=C_{27}H_{30}N_2O_3+3H_2O;$$

and from this again, by the action of heat, another base which is isomeric with the last, named *ethylsalidine*, the platinum salt of which was prepared and analysed.

By the action of nitric acid upon the hydride of ethyl-salicyl, two bodies appeared to be formed; the first is a yellow oil, heavier than water, assumed to be the *hydride of nitro-ethyl-salicyl*, and the ultimate product gave on analysis numbers corresponding to those demanded by ethyl nitrosalicylic acid. Their production was thus accounted for—

$$\text{I. } C_7H_5(C_2H_5)O_2+HNO_3=C_7H_4(NO_2)\,C_2H_5)O_2+H_2O.$$

$$\text{II. } C_7H_4(NO_2)(C_2H_5)O_2+O=C_7H_4(NO_2)(C_2H_5)O_3$$

The second stage of this oxidation was said to be analogous to the conversion of aldehyde into acetic acid.

The author further described the compounds resulting from the actions of the iodides of allyl and amyl respectively upon hydride of sodium-salicyl (salicylate of sodium), and concludes with some interesting theoretical considerations arising out of the results of his investigation. It is thus proved that the replacement by alcohol radicals, of the hydrogen usually regarded as alcoholic in the hydride of salicyl, does not in any way interfere with its aldehydic characters. The formation of hydrosalycylamide from the same hydride by the action of ammonia affords, on the other hand, a demonstration of the fact that its properties as an alcohol or hydrate remain unimpaired.

Dr. J. H. Gladstone communicated some further particulars of his research "*On Pyrophosphoric Acid.*" According to Graham's original view of the constitution of this acid, when regarded as $2HO,PO_5$, it was believed to be a bibasic acid. Since the atomic weight of oxygen has been doubled its formula is written $2H_2O,P_2O_5=P_2H_4O_7$, and it becomes a tetrabasic acid. The correctness of the latter view receives support from the existence of amides containing one, two, and even three molecules of NH_2 in the place of HO. The present paper treats of some normal pyrophosphates and certain allotropic modifications of these salts, and indicates the constitution of the acid as deduced from several modes of formation. The author confirms Schwartzenburg's analysis of the ferric pyrophosphate, $P_2fe_4O_7+3H_2O$,* and suggests the existence of a soluble double salt $P_2Na_2fe_2O_7$. The cupric salt was found to have a similar composition, but contained only two atoms of water. Dr. Gladstone mentioned some remarkable facts tending to establish the existence of an allotropic ferric pyrophosphate. Thus, if a solution of sodium pyrophosphate be mixed with a large excess of sulphuric acid and ferric chloride then added, there is no precipitate in the cold, but, on heating, a white flocculent compound is formed, which differs from the ordinary modification of that substance by being insoluble either in dilute mineral acids, ferric chloride, or in alkaline pyrophosphates. A quantity of this substance was prepared and analysed. Its composition was found to be identical with that previously recognised—viz., $P_2fe_4O_7,3H_2O$. It is proposed to use this reaction as a test for the acid in question. Similar results were observed in the case of copper. Regarding the modes of preparation, it is stated that the pyrophosphates had hitherto been obtained by the action of heat upon the orthophosphates, but Dr. Gladstone succeeded in producing them by dissolving phosphoric anhydride in an alcoholic solution of hydrate of potassium or other alkaline base; or if the oxychloride of phosphorus be dropped into a strong aqueous solution of the same hydrate the product was identical. That this result is true in the case of the strongest ammonia, had been previously shown. The author concluded by tracing the formation of pyrophosphoric acid in stages, as follows ;—

$$\text{I. } PCl_5+H_2O=PCl_3O+2HCl.$$

$$\text{II. } 2\left\{\begin{array}{c}Cl\\PClO\\Cl\end{array}\right\}+H_2O=2HCl+\left.\begin{array}{c}PCl_2O\\PCl_2O\end{array}\right\}O$$

$$\text{III. } \left.\begin{array}{c}PCl_2O\\PCl_2O\end{array}\right\}O+4H_2O=4HCl+\left.\begin{array}{c}P(HO)_2O\\P(HO)_2O\end{array}\right\}O$$

Pyrophosphoric acid, $P_2H_4O_7$.

The limited space at our disposal in the present number compels us to defer until next week a full account of the remaining communications.

The titles of the other papers which were read at the meeting were:—"*Water Analysis; Determination of the Nitrogenous Organic Matter,*" by Messrs. J. A. Wanklyn, E. T. Chapman, and Miles H. Smith. "*Analysis of a Biliary Concretion, and on a New Method of Preparing Biliverdine,*" by Dr. T. L. Phipson. "*The Action of Chloride of Iodine on Picric Acid,*" by Dr. John Stenhouse. "*On Julius' Chloride of Carbon, C_6Cl_6.*" by Mr. Henry Bassett.

The President moved a vote of thanks to the authors of these communications, and adjourned the meeting until after the recess.

NOTICES OF BOOKS.

Analysis, etc., of Coal Gas. By Rev. W. R. Bowditch, M.A., F.C.S. London: E. and F. V. Spon, 16 Bucklersbury. 1867.

Nothing in the history of chemistry offers a parallel to the extraordinary series of results obtained by the close study of the products of the distillation of coal. The matter has been treated by almost every chemist of eminence, and an endless series of new products have enriched the philosopher, chemist, physician, economist, photographer, and dyer. No worthier or abler historian of coal gas, as regards its purification and use, could well be found than Mr.

---

* Ferricum (fe)—18·66. (Williamson.)

Bowditch, who has, year after year, by his discoveries fairly earned the name of a public benefactor. The chemical readers will obtain from Mr. Bowditch facts not to be found elsewhere, and before unknown to him, and also a more forcible expression of fragmentary knowledge contained in scientific works, in which diffusion of matter is so often unavoidable, and whose only remedy is a compilation of this kind. The book is of necessity, as regards its mass, a compilation, but it is also a comparison of the author's own results with those of other authors, whether antecedent or subsequent.

Perhaps the greatest, certainly the most obvious, of the benefits for which we have to thank Mr. Bowditch, is the attention that he has drawn to the effects arising from carburetting or naphthalising gas. Indeed, if we mistake not, the spirit of the present works points to a division of labour—to operations necessary at the place of manufacture, not to be confused with others more expedient at the place of consumption—but a strong and forcible expression of this is wanting. On the question of carburetting gas, we find: "The large proportion of carbon in naphthalin pointed it out as being fitted to yield much light with little heat, if it could be burnt. But only a short time ago it was the prevailing opinion among chemists that naphthalin could not be so burnt. At the instant of liberation it crystallises, and so clogs the pipe, being regarded by the manufacturer as a waste product only—and a very inconvenient one too. Experiment also proves that ordinary gas at common atmospheric pressures and temperatures has no power to combine with the crystallised naphthalin." With these facts in mind, Mr. Bowditch contrived an apparatus, which he fully describes, on the principle of using naphthalin when in an available state—*i. e.*, not as a solid; and this object is effected by the gas burner itself, which so by its own waste heat supplies to itself increased light—a simple device, but, as will be shown, of great practical application. Carbolen is used for the apparatus, a commercial general term for these heavy oils, differing so little from naphthalin that the latter, as being a definite chemical body, is taken as its type. A gallon of this, weighing 10 lbs., costing 2s. 6d., yields a light of 14,000 candles. As a simple tabulated result we find—

	Weight burnt.	Light.	Cost. £	s.	d.
Naphthalin .	10 lbs.	14,000 candles	0	2	6
Gas . .	280 lbs.	14,000 "	1	17	4

For equal *weights* the heating powers of gas and naphthalin are as 12,000 to 8,786. But add to this fact one more important still—or rather the sister fact to it—viz., that all the carbon added by the method gives light, and so lessens the amount of gas used. No unnecessary carbonic acid being formed from the marsh gas and carbonic oxide unused (if not carburetted) for lighting purposes, the smaller quantity of carbonic acid, of course, as will be at once seen, is not so as a total result, but is so per unit of light, an excess of the material being thus avoided.

The reader will grant also to the author his other two statements of minor importance—first, the greater steadiness of carburetted light; for "highly carburetted gas cannot be burnt without burners of small aperture and under considerable pressure, without smoke and diminished light"—these are the very conditions of a steady light. The second point is that by the light of carburetted gas we can distinguish colours with almost the same ease, distinctness, and accuracy as by daylight—this as a result of quality, not of more quantity of light.

This also the chemist might expect; but he could not expect the following strange result:—"In fact, the spectrum of my light approaches the spectrum of sunlight more nearly than that of any other artificial light does." The materials used by the inventor of the apparatus are cymol and naphthalin—both very cheap and abundant. As regards the safety of these materials, "they will not burn alone, but require the heating power of a combustible gas to sustain the combustion. When lighted matches, candles, etc., were plunged into the materials at 100° C., the lights were extinguished as they would have been by immersion in water, and in no instance were the hydrocarbons ignited." The officers of insurance companies state that they are unacquainted with anything in use as an illuminant which is so safe. To conclude the question, Laurent has found that naphthalin thrown into a red-hot crucible volatilises undecomposed, and condenses in the air in snowy spangles. For our part we should like to know if any purification of the so-called carbolen is required for the separation of the sulphur which is taken up by naphthalin in very notable quantity, and what is the extra cost involved by such purification. If the crude oil is to be used, it would be necessary to purify from sulphur at the place of manufacture; otherwise, for the same amount of light, if the carbonic acid be less, the sulphurous acid will be more, and poisoning by the former is preferable to the same result by the latter, with less general destruction of property.

We have followed Mr. Bowditch so fully in this portion of his work that we cannot treat other most interesting subjects at the same length. It is sufficient to say that the same comprehensiveness and enthusiasm in the subject are features common to every chapter. A full history is given of M. Berthelot's synthesis of acetylen, and the great chain of results hanging upon that discovery up to the time when the book went to press. One fact, stated in a very modest way, will doubtless be thought worthy of greater interest by insurance companies. We allude to the proved gnawing of gas-pipes by rats as a probable explanation of sudden gas explosions, caused, of course, as it was formerly said, by carelessness in turning off the gas. A diagram of a pipe so injured is appended. An iron pipe it was; but the dangers attending lead are of course much greater.

Methods are given *seriatim* for tar-testing in coal gas. "Some of the oils so dissolved from gas are of such a high boiling-point that they cannot be distilled, except at a temperature which *softens Florence flasks*, and their density is far greater than [that of?] water." Kraut's flame test for ammonia in gas by combustion is quoted from the Chemical News, No. 311; also, Dr. Hofmann's original demonstration of the inflammability of ammonia. The author remarks:—"I must caution inexperienced manipulators against buying their test-papers. I have seen purchased turmeric paper, held in a full stream of scandalously ammoniacal gas for more than a minute, remain perfectly unaffected; whereas properly made paper became red-brown in a single second. Managers and boards of directors have been so known to have been deceived."

As regards the difficulty of obtaining tri-ethy-phosphine for testing for bisulphide of carbon, it is remarked that it is not sold as an article of commerce, and only experienced chemists can make it. Mr. Bowditch has known 5*l.* to have been offered and refused for an ounce of this compound. It is therefore practically inapplicable as a test. This makes Mr. Bowditch's own test for the same compound by solution in alcohol, and subsequent dilution by water, the more valuable. A figure of the necessary apparatus is given, with a full description. The author has also thrown much light upon sulphur generally in gas, founded upon the power (as our readers doubtless remember) of heated lime to *act upon all* the sulphur compounds in gas. Of course, the origin of such sulphur is not learnt thus. As regards sulphur testing, we come to some statements that will be of the greatest interest to chemists. "I have passed this sulphur compound into *nitroprusside of sodium* for some time, and have failed to have obtained any indication of the presence of a sulphide; and *yet lead paper has been coloured.* I think I can name the compound, and, indeed, I have done so to friends in private; but as I am not prepared here to give proof of the accuracy of the conjecture, I forbear." Also, from steps in the process specified, the author continues:—"I therefore conclude that the blackening of the lead paper in the above case was not due to hydrosulpho-carbonic acid, but to some unknown or unsuspected compound."

Mr. Bowditch has found by experiment that when the test candle is thinned, *either an increase or decrease* of consumption may result—which is very satisfactory to us, for it serves to show that, apart from the clumsiness and inaccuracy of expression involved by the use of the term "so many candles," a positive radical evil attends their use. Arago by his photometer was on the more trustworthy track, and to his method, improved so as to be practically worked, all experience tends to point. The author gives us the outline of a new and ingenious scheme for the improvement of the use of candles, which he calls "the new photometric candle balance and elevator;" we hope, however, that he will turn his energies to the question of examining light by any refractive or polarising means, admitting of a concise expression of results. It will not be the first time that Mr. Bowditch will have rendered a useful original process useless by a subsequent and more perfect one.

Ure's Dictionary of Arts, Manufactures, and Mines. Edited by Robert Hunt, F.R.S., F.S.S. Fifth Edition. Chiefly rewritten and greatly enlarged. 3 vols. Longmans.

A Dictionary of Science, Literature, and Art. Edited by W. T. Brande, D.C.L., F.R.S.L. and E., of Her Majesty's Mint, and Rev. George W. Cox, M.A., late Scholar of Trinity College, Oxford. 3 vols. Longmans.

The new editions of these two well-known dictionaries, each consisting of some 3000 pages, and each dealing largely with chemistry, are now before us, and it behoves us to offer some criticism upon them. Few tasks could be more difficult. We might indeed, with perfect honesty, confine ourselves to general praise, speak of the great difficulties which attend the compilation of such works, and point out the number of admirable articles, and the vast mass of important information which each contains. But if we approach the work of criticism, and, while bestowing fair praise on their many excellences, endeavour to point out some of their faults of fact and arrangement, we are met by the fear lest, our praise being necessarily vague while our objections must needs be specific, we should end by leaving upon our readers' minds an unfair impression of the true worth of the books. The criticism which employs itself in picking out small errors and blemishes from a substantially good book, arraying them in rows, and parading them before the eyes of the world, is unfair and ungracious, and cannot be atoned for by any amount of indefinite praise. We should be sorry to be betrayed into injustice of this kind, and shall therefore deal as lightly as possible with minor blemishes, and shall only point out errors of fact when they appear to go hand in hand with faults of method.

Two general objections will, however, suggest themselves to the chemist, on his first glance at the new dictionaries—for new they are, to all intents and purposes. One of these, indeed, they share with but too many modern works of reference. Original authorities are not quoted in either book, nearly as often, or as fully, as they should be; and this, we fear, will curtail their usefulness to scientific men in a marked manner. To select an illustration at random. Suppose a chemist wishes to "read up" Madder. He turns to Ure, and there finds an excellent article by Dr. Schunck, in which the results of Persoz, Runge, Robiguet, and many other experimenters, besides those of the writer, are chronicled; but scarcely in one single instance will he find a direct reference to the memoirs in which those results were first announced. This is hardly fair. The original memoirs are often just what the chemist wishes to get hold of, and he has a right to expect that his dictionary shall help him in what is generally a troublesome and laborious search.

The other objection is a less serious one. We, of course, are not likely to quarrel with editors for putting too much chemistry into their books, but we cannot but think it would have been better to have left to treatises on pure chemistry a good deal that is included in these volumes. Would it not have been better, for instance, in a technological work like Ure, to have omitted such articles as "atoms," "atomic theory," "combining numbers," and "equivalents"? And what possible object can there be in describing such compounds as "hederic acid," "ambreic acid," "chloriodoform," "pittacal," and "anisidine," all of which, and many more as unimportant, are to be found in one or other of the dictionaries? When every line of space is so valuable, the greatest care should be exercised in the selection of matter, and the excision of these irrelevant subjects would have allowed of a fuller treatment of many which now fare badly.

And now, could we but afford the space, we should enter upon a more detailed examination of the works before us. Mr. Robert Hunt, the editor of "Ure," has done his work conscientiously and well, and each of his volumes is crowded with articles of the utmost interest and importance to the practical chemist. We can do no more than give the titles of a few of them. "Coal-gas," an admirable treatise, 60 pages long, by Dr. Frankland; "Bread," by Dr. Normandy; "Bleaching," and "Calico-printing," "Caoutchouc," "Manure," by Dr. Voelcker; "Sugar," by Mr. Fryer; "Candles," "Glass," "Disinfectants," by Dr. Angus Smith; and "Naphtha," by C. Greville Williams, are all elaborate and most valuable articles. Mr. Greville Williams's contributions to the work are numerous and uniformly well written. Dr. Schunck and Dr. Noad have likewise been large contributors, the article "Iron," by the latter, occupying over 80 pages.

The smaller articles, though frequently leaving much to be desired, are on the whole satisfactory. They seem generally to have been compiled with care, and the editor has wisely allotted them a fair proportion of the space at his command, and has not suffered them to be entirely swamped by the more important ones. We are, nevertheless, inclined to believe that they might advantageously have filled an even larger proportion of the book than they do: for the true province of a book like this is to supply knowledge which cannot easily be obtained elsewhere, and important manufactures usually have special treatises devoted to them, whereas the others can only hope to find their places in a work of reference. We have purposely said nothing of some very important sections of the book. The metallurgy alone would form a good-sized manual, and the descriptions of machinery and mechanical processes are probably quite as extensive; but our task would be even more hopeless than it it is now, if we attempted to comment on subjects such as these. We leave the book safely to our readers' criticism, convinced that very few chemists will be able to do without it.

"Brande's Dictionary," the republication of which is only just completed, is very different from the preceding work in object and execution. Much of it, of course, deals with subjects with which we have no concern, and upon which we have no right to speak; but as chemistry, naturally enough, occupies a somewhat prominent position in it, we have a fair *locus standi*. We, indeed, almost wish we had not, for the respect which every chemist must feel for the memory of its original editor makes it an unpleasant task to disparage it. But the truth must be told, and although we admit very cheerfully that many valuble chemical articles are to be found in it, it is on the whole a most unsatisfactory epitome of modern chemical knowledge. In regard to theory this is not to be wondered at. No one expected any very cordial recognition of "croquet-ball" atoms, though we might have begged that our teeth might not be set on edge by barbarous and long-exploded definitions and doctrines coeval with Lavoisier. But we surely have a right to expect accuracy in facts. We do not complain that there are so few formulæ in the book, although the most out-of-the-way compounds are described. We will not quarrel with CH_2 as a representation of marsh-gas or C_4H_3 for acetyl, and we will only object on the score of convenience to our old friend CS_2 being described as carburet of sulphur! (we only found the compound by chance), but we must assert in the most earnest manner that the atomic weight of chlorine is *not* 36, nor that of idone 126, nor that of bromine *about* 78.

And, moreover, if we concede C_4H_3 as the formula for acetyl, we must refuse our assent to the further proposition that acetamide is "derived from ammonia by the replacement of one equivalent of hydrogen by acetyle. There is, it appears, a species of lead poisoning to which compositors are liable, and which is called "wrist-drop." "It may be cured," we are told, by soaking the hand in a solution of potassium and eliminating the lead." We do not attempt to deny it; but we anticipate some difficulty in applying the cure.

Principes de Chimie, fondée sur les Théories modernes. Par A. Naquet, Professeur agrégé à la Faculté de Médecine de Paris, &c. 2e édition, considérablement augmentée. Paris: Savy. 1867.

Leçons élementaires de Chimie moderne. Par M. Ad. Wurtz. Doyen de la Faculté de Médecine de Paris. Premier fascicule. Paris: Masson. 1867.

Traités Elémentaires de Chimie Médicale. Par Ad. Wurtz, Parts I. et II. Paris: Masson. 1864-5.

M. Naquet's little book, published less than two years ago, has already reached a second edition, and we are glad to find that the author has taken the opportunity of increasing its bulk very considerably. The book is no doubt well known to many of our readers, and we believe that no one who has seen it will hesitate to join in our cordial praise of it. It is a well written, clear, and succinct account of the leading doctrines of modern chemistry, and is, in the best sense of the word, an original work. We do not not mean that the author has invented a new system of classification, of nomenclature, or of notation, or that he crowds his pages with records of his own discoveries, but simply that every chapter he writes bears the stamp of individual thought—that the facts and theories he describes are presented, not as raw material cut by a compiler's scissors from a hundred different sources, but digested, assimilated, and, so to speak, organised in the brain of an author who takes the trouble to make a thing his own before issuing it to others. The book is too well known to require a detailed description from us, even if we could afford the space for one, and we will content ourselves with glancing at a few of the new additions.*

M. Naquet, wisely, as we think, devotes a hundred pages at the beginning of his book to laws and general principles, thus dissenting from the fashion which appears to have taken root in England of interspersing everything of the kind, theories of atomicity, rules of nomenclature, laws of combination, and the like, among the sections on the history of the elements. Many portions of this introductory matter have been entirely rewritten, and all have received some modification. At page 22 we find an historical sketch of the great "dissociation" controversy, the author finally giving in his adhesion to that remarkably convenient discovery. The section on the atomicity radicals contains, of course, an account of Kekulé's views very clearly stated. Hofmann's term "quantivalence" is adopted, and is employed as distinct from "atomicity," the atomicity of an element being regarded as invariable, while its quantivalence may be subject to change. We think the author has made a mistake in devoting three pages to the absurd hypothesis of sub-atoms invented to account for the observed variations, in atomicity, but we can easily pardon it for the sake of the distinct rejection which is accorded to it. We are disposed to agree heartily with the following passage from M. Naquet: "Quant à nous, ne voulant pas aller au delà des faits, nous admettons que des molécules non saturées existent à l'état de liberté, parce que l'oxyde de carbone et beaucoup d'autres corps en fournissent les preuves, et nous admettons aussi que les radicaux d'atomicité impaire peuvent exister sans se doubler, parce que cela a lieu pour le bioxyde d'azote AxO, et l'hypoazotide AzO_2." †—Page 48.

With respect to two of the gravest difficulties on the new views, the compounds $AgNaCl_2$ and ICl_3, our author rejects Kekulé's hypothesis of "molecular combination," and prefers to regard chlorine and iodine as being triatomic. The wisdom of such an assumption is, however, extremely questionable.

In the section on acids, bases, and salts, the views of Cannizzaro, Wurtz, and Kekulé are described with a clearness which we have never seen surpassed. No student could have the least difficulty in mastering them.

Before leaving the book, we must, however, advert to one or two somewhat important omission—omissions which surprise us in such a carefully edited manual. In the account of ozone the fact that when the ozone is absorbed from ozonised oxygen, no contraction of volume is observed, is duly noted, and the hypothetical explanation of this fact suggested by Dr. Odling—namely, that the true formula for ozone is O_2O, and that the removal of one atom of oxygen, therefore, leaves the volume unchanged—is likewise given; but the beautiful experimental verification of this hypothesis recently supplied by M. Soret, we succeeded in absorbing the whole molecule of ozone by oil of turpentine, is unaccountably omitted. The other omission is even more important. The author is evidently ignorant of the splendid memoir of H. Kopp an atomic heats, which was published in the *Philosophical Transactions* for 1865. The result is, that he not only assumes the atomic heats of all elements except carbon, boron, and silicon, to be identical; but he makes the grave mistake of deducing the molecular constitution of water from the specific heat of water, instead of from that of ice.

M. Wurtz, two of whose manuals we take this opportunity of noticing, is certainly a most diligent writer. Besides his completed works, he has three books at present in progress. The titles of two of them are given at the head of this article, while the third, a large dictionary of chemstry, is announced for speedy publication. Of the *Chimie Médicale* two parts have already appeared, one devoted to inorganic, the other to organic chemistry. The third, on "Chimie Biologique," has been expected for some time. As far as it has gone, it is a very good and practical work. Its title, however, hardly gives a true idea of it, for it is simply a manual of chemistry, well written and arranged in a clear though somewhat old-fashioned manner. The only thing peculiar about it is that all subjects especially interesting to medical men, such as mineral waters, substances used in pharmacy, the detection of poisons, and the like, are brought into marked prominence, and are treated in great detail. Strange to say, the old equivalents are employed throughout. The author apologises for it in his preface, by alleging the necessity of conforming to the official teaching of Paris; but HO, in a work by M. Wurtz, seems almost as much out of place as an account of phlogiston would be.

Only one part of the *Leçons* has as yet reached us, and it is not of a character to call for any particular remark. It is simple, clear, and concise; but though the new atomic weights are adopted in it, it lacks the original and scientific arrangement which distinguishes M. Naquet's *Principes*. In spite of some advantages, we cannot but regard it as far inferior to the last-named work.

Theology and Natural Science; their Mutual Relations. A lecture by J. H. Gladstone, F.R.S. Jos. Nisbet and Co.

Dr. Gladstone has endeavoured to show in the present lecture how the study of natural science, being the study of one volume which has issued from the Divine Being, prepares the mind for the reception of the truths delivered in the companion volume of God's word. Both are difficult studies, and, in many cases wrong interpretations are arrived at; but the fact that the interpretation of the one record, clashes with the apparent meaning of the other, shows not

---

* We are glad to hear that a translation of the new edition is in progress, and will be published before long.

† Nitric peroxide has been shown to dissociate below 70° C., and Dr. Frankland (Lecture Notes, p. 61) tries to get over the NO difficulty by regarding it as N^2O^2 dissociated at a very low temperature. But if this were the case it could only dissociate into NO and NO, and the obnoxious compound must, therefore, at ordinary temperatures, contain diatomic nitrogen.

that the original works are inconsistent the one with the other, but that our interpretations in neither case are perfect. All the inspired teachers of religion have drawn lessons from the study of nature, whereas Nature has acted the part of a terrible giant, a destructive Jupiter, or an awful Thor, in the religions that have had no revelation. Science repays the debt by clearing the mind from superstition, by exciting an earnest reverend spirit, by inducing humility of mind, clearness of definition, calmness of judgment.

The slur cast upon science, that it leads to infidelity, is well rebutted by Dr. Gladstone. He states it as his experience that there are no more irreligious men in the walks of science than in other professions. What a man is before he begins to study, that he remains. The religious man becomes more firmly convinced, the irreligious man gains greater scope for scoffing. Science is not necessarily religious, nor is it the reverse; it may be conducive to either end. Dr. Gladstone has spoken kindly, thoughtfully, and well on one of the questions of the day that touches us not as scientific men, but as *men*, who cannot be indifferent when it is sought to place science in opposition to religion.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

NOTICES OF PATENTS.

2110. *Treating Fatty and Oily Matters.* G. PAYNE, Battersea. August 16, 1866.

AN increased quantity of fatty acids is thus obtained. After the breaking up of any fat into its acid, and glycerine as its base, by sulphuric acid. as a further treatment the fatty acid is combined with an inorganic base (as litharge or potash), and then, by a stronger acid, the fatty acid is again liberated and may be distilled off.

2101. *Steel and Iron Manufacture.* J. CAMERON, Mount Pleasant, Barrow-in-Furness. August 15, 1866.

THE Bessemer process is modified by the use of lime, calcic, barytic, sodic, potassic, and ferric carbonates; with other iron ores, fluor spar and salt, as fluxes.

2083. *Production of Green Colouring Matter for Dyeing and Printing Textile Fabrics and Yarns.* J. A. WANKLYN, City, London, and A. PARAF, Manchester. August 14, 1866.—Not proceeded with.

EQUAL weights of rosaniline and an alcohol or suitable solvent are taken, with ethylic or isopropylic iodide (or other replacer of hydrogen), and are subjected to a temperature 230° Fahr. for three hours under pressure. The solution of sodic carbonate (one percentage strength) is added to the product in the proportion of four times its weight. There results a green dye in solution, and violet dye as a precipitate. The latter is converted by soda ley into a nearly colourless base, with violet salts. The base is powdered again, heated to 230° Fahr., and treated as before, more green solution resulting, and so on for two or three times until all is convered into green dye.

2115. *Use and Application of an Inorganic Glyceric Ether.* A. PARAF, Manchester. Dated August 17, 1866.

DEPENDS on the formation of a neutral arsenite which is of value in madder dyeing. Arsenious acid of commerce is dissolved in an equal weight of glycerine. This so-called arsenious glycerine ether, with residual arsenic dissolved in glycerine, easily decomposes in presence of steam, leaving the insoluble arsenious acid. 1 lb. of the ether mixed with 2 oz. of any crystallised aniline colour is dissolved in starch solution; steaming for about half an hour deposits the acid, and fixes the colouring matter in a printed textile fabric.

Communicated by Mr. VAUGHAN, F.C.S., PATENT AGENT, 54, Chancery Lane, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

133. W. Weldon, Park Villa, West Hill, Highgate, Middlesex, "Improvements in the manufacture of chlorine, and in the production of artificial oxides of manganese for employment both in that and other manufactures."—Petition recorded January 18, 1867.

284. J. Buhrer, Munich, Bavaria, and A. P. Price, Lincoln's Inn Fields, Middlesex, "Improvements in effecting the distillation of coal, shale, wood, peat, and other bituminous or carbonaceous substances."—February 1, 1867.

1122. J. Hargreaves, Appleton-within-Widnes, Lancashire, "Improvements in the manufacture of steel and soft iron from cast iron."—April 16, 1867.

Lankester, Peckham, Surrey, "Improvements in the manufacture of colours and the extraction of colouring and dyeing matters from coal oil, shale oil, or coal tar, combined with peat or turf, and for a combination of any of these substances, and also for the utilisation of the residue for the purpose of what is known as moulders' blacking, after the colouring and dyeing matters have been extracted." —April 20, 1867.

1295. J. Heaton, Langley Mill, Derbyshire, "Improvements in the conversion of cast iron into wrought iron, part of which improvement is also applicable to the conversion of cast iron into steel."—May 3, 1867.

Patent Vital Force.

The great mystery of life, that sages have meditated upon, and philosophers wondered at, in all ages—the Archæus of Paracelsus, the Anima of Aristotle, the Vital spirits of the older physiologists—has at last been cleared up by a brilliant genius who resides in Paris. M. Martin Ziegler has not only demonstrated the existence of a "vital fluid," but has even made the astounding discovery that it is disengaged "whenever azote and carbon are brought into contact." His method is simple—all grand truths are simple —he immerses a porous cell containing ammonia in a vessel filled with treacle! The end of a silk thread is placed in each, and then, on connecting them, "the circuit is closed, and the current of vital fluid passes," capable of producing "on an animated being very considerable effects." No wonder the lucky inventor rushed off and patented his invention at once. He does not, it is true, tell us the precise nature of the "very considerable effects" which he is able to produce, but we can of course have no difficulty in guessing at them. We picture to ourselves the tottering steps and shrivelled limbs of the scarce "animated being," who will seek the patentee's laboratory, his stock of "vital fluid" well-nigh exhausted, and we see him return, after a brief exposure to the life-giving treacle, with the energy and fire of manhood's prime, and with a stock of "vital fluid" enough to last for another fifty years! We can fancy the inventor, with a cask of treacle and a carboy of ammonia, operating at the Morgue before a distinguished assemblage, and bringing back the warm tone of life and health to the cheeks and limbs of the ghastly corpses arranged there. Nay, the experience of Pygmalion himself seems hardly incredible in the light of this new discovery.

We could wish, however, for a little more detail. We should very much like to learn the equivalent in treacle of the vital force of an average man. How many pounds of treacle would be required to bring a man from seventy back to twenty? Would rejuvenescence be a *very* expensive process? And we feel no little anxiety to know whether we are justified in going on living without paying a royalty to M. Martin Ziegler.

We have not been playing upon our readers' credulity. The patent we have been describing has actually been granted to the well-known patent agent Mr. Brooman. Its date is October 3, 1866, and its number 2536. We recommend our readers to examine it, for a more powerful satire on the present state of the patent laws we have never seen. From the following quotations the character of the document can be told:—

"Whenever azote and carbon are brought into contact, whether an azoted body and a carbonated body, or even a body strongly azoted and another which is only feebly azoted, there is disengaged an imponderable fluid, the presence of which is made known by particular effects on the organism of living things, animal or vegetable. This fluid, which the present inventor calls the vital or organic fluid, is thus a new agent generated in the midst of chemical circumstances, like heat, light, and electricity. It is collected, manifested, and transmitted by currents like the electric fluid, as hereafter explained, but notwithstanding that the phenomena by which it manifests itself have a certain analogy with electric phenomena, this vital or organic fluid has really an existence of itself, autonomous and independent, and the best proof of this is, that its currents can pass through conductors which are insulating for electricity. . . . .

"Azoted bodies are those which are the best conductors of the vital or organic fluids, and among them preference is given to silk, which has the advantage of intercepting the electrical currents, the intervention of which would be inconvenient. As insulating bodies of the vital fluid I may mention glass, enamels, and minerals in general.

"The present inventor has also observed that if an acid or an alkali be made to act upon an organic matter a large quantity of vegetable or organic fluid is disengaged; also that if the organic matter is devoid of azote the disengagement of the fluid takes place if an acid or an alkali be made to react upon a hydrocarburet, or even upon carbon.

"I now proceed to describe several arangements of apparatus for producing the vital or organic fluid, which are comparable in one point of view with voltaic piles or batteries. . . . .

"The following is a good arrangement:—A porous vessel or bladder is filled with caustic ammonia and immersed up to the neck in molasses contained in an ordinary vessel; a silk thread is attached to the neck of the porous vessel or bladder, and the end of a second silk thread is placed in the molasses; the two ends of the silk threads being connected, the circuit is closed, and the current of vital fluid passes; its effect will become manifested on an organised being in the line of the current. If a certain number of these elements are gathered together in couples, a dozen for example, by plunging the thread from the ammonia of the first element in the molasses of the following element, and so on, or by connecting on the one side all the threads from the ammonia, and on the other all those from the molasses, a powerful current will be obtained, which produces on an animated being very considerable effects."

CORRESPONDENCE.

Transparency of Red-hot Metals.

To the Editor of the Chemical News.

Sir,—Every reader of your valuable journal would note with interest, in your last week's impression, a letter upon the above subject signed "A. Adriani," but very few, I think, would endorse the author's opinions. With regard to Father Secchi's discovery of a crack in the interior of an iron tube by (seeming) transparency, is it not more likely that the crack exhibited itself because where it existed the metal would be thinner than throughout the rest of the tube, and would therefore cool more rapidly, becoming in consequence darker coloured, thus showing on the exterior both its extent and direction?

I am, &c

W. F. K. Stock, F.C.S.

Laboratory, Darlington.

South Kensington Science.

To the Editor of the Chemical News.

Sir,—Can you or any one else tell me the meaning of *Science* in the South Kensington vocabulary, and why it should always be coupled with the word *Art* when it is spoken of west of Hyde Park Corner? What possible connection is there between the two? and what occult reason is there that the public should have the idea incessantly dinned into them that the same faculties which have given us steam, the telegraph, the soda trade, and aniline dyes, are so intimately connected with Majolica Ware and Old Masters that they must perpetually form a binary compound of "Science and Art," as inseparable as "Box and Cox," "Pyramus and Thisbe," or "Medes and Persians?"

I rather suspect the true interpretation is this. The practical English public don't much care for Art, but they *do* care for Science; so the latter is tacked on to the former to make it go down. If this is not the reason, and if *Science* is really valued at South Kensington, the officials there have shown a most unappreciative spirit in keeping it so much in the background as they did at the late inauguration of the Albert Hall of Science and Art.

I was one of the spectators there. I noticed numerous *Art* celebrities and official personages in seats of honour, but poor *Science* had to content itself in the crowd.

I am, &c., F.R.S.

[Our correspondent evidently had not a good "standpoint" in the crowd, or he would have seen two or three scientific men in reserved seats. We cannot say we feel the same indignation which our correspondent expresses at the non-recognition of science. English science requires no petting to enable it to flourish, and can exist in a healthy state without official patronage.—Ed. *C. N.*]

A Good Suggestion.

To the Editor of the Chemical News.

Sir,—Would you allow me, through the medium of your valuable journal, to make a suggestion? I would suggest that chemical students should learn some system of shorthand. This art is easily acquired. If the student would devote, say, an hour daily, or two hours a day three times a week, to learning and practising, he might attain such a degree of proficiency as would enable him in the course of three or six months to write at the rate of 80 to 90 words per minute. This rate would be sufficient for the purpose of taking notes at lectures, or, indeed, reporting most lectures verbatim. Shorthand writing will be found useful on many occasions—for instance, jotting down thoughts arising on the spur of the moment, and for making memoranda intended to be read by yourself only. Many other uses would suggest themselves for the employment of this art. Of course, to follow a very quick speaker and report his speech word for word, much time must be devoted to hard practice. I was able, after six months' practice, to write at the rate of 100 words per minute; many, however, find it impossible to go beyond 80 words.

The system I recommend is Pitman's "Phonography," which is written according to sound. Nothing, I am convinced, strengthens the memory so much as the use of shorthand. I have often attended lectures and taken down the greater part of them and the discussions arising, and have found, on coming to transcribe my note into longhand, that I could do so with but seldom looking at the shorthand notes.

I trust many of your readers may be incited to learn the art of shorthand. The books required are cheap, the time taken to learn shorthand, especially Pitman's, is short, and it can be done without a teacher. I think that by drawing attention to this subject much good may be done.

I am, &c. J. H. Swindells.

Edible Earths.

To the Editor of the Chemical News.

Sir,—I notice in a recent number of your journal a paragraph containing the analysis of a species of clay eaten by the natives of Borneo, and where it is asserted that "no other analyses of any substances used as such have been made, or at least published.

Perhaps you will allow me to state that Vanquelin formerly analysed the clay eaten by the Ottomacs (Humboldt, "Ansichten der Natur"), and that an analysis by Dr. Trail of an earth used as an aliment is given in one of my works ("Utilisation of Minute Life"), where the results of another analysis by Liebig are also alluded to. Finally, I beg to subjoin my own analysis made in 1865, of the earth which is extensively mixed with flour in Umea Lapmark in periods of scarcity:—

Water and organic matter	15·0
Silica	80·0
Sand	0·9
Alumina and oxide of iron	3·5
Carbonate of lime	0·6
	100·0

I am, &c. T. L. Phipson, Ph.D.

London, May 26.

Transparency of Red-hot Metals.

To the Editor of the Chemical News.

Sir,—In reference to the above subject, I may state that platinum, at least, appears to me transparent when it is at a strong white heat. If some carbonate of sodium is fused in a thin crucible, and then raised to a very high temperature, on shaking the crucible the motion of the fused salt may be discerned *through* the sides of the crucible.

I am, &c. W. B. G.

Liverpool, June 3.

[This is more probably due to the fact that the platinum cools more rapidly where not in contact with the fused salt than it does where the salt touches it.—Ed. C. N.]

To the Editor of the Chemical News.

Sir,—As to the transparency of some metals at bright red heat, workers in metals know it pretty well. Molten copper poured out of a ladle in a thick stream is as transparent as glass. I was acquainted many years ago, while at Utrecht University, with a gentleman residing there, who was the owner of an extensive establishment for rolling copper, etc.; the quantity of metal usually molten down at once exceeded ten tons in weight, and the workmen, among other tests about the proper degree of purity of the metal (*i. e.* freedom from suboxide), used to pour out 100 kilos. in a stream, the thickness of which was fully from 1 to 1·7 centimètre, and was as perfectly transparent as glass, with a slight bluish hue. Copper in bars heated for forging is the same; iron and platinum far more so; while gold 0·7 centimètre thick presents the same property; silver does not become transparent.

I am, &c. Dr. Adriani.

[We still think these alleged facts require verification by scientific men accustomed to exact observation.—Ed. *C. N.*]

Science and Art.

To the Editor of the Chemical News.

Sir,—Your correspondent "F.R.S." wants to know the

Brompton meaning of the wood "Science." A good many would like to know the exact sense in which "Art" is there used. "F.R.S." and the majority of the public appear to associate it only with painting, sculpture, etc. But from the mysterious addition of a final *s*. which has lately taken place (*e. g.* Albert Hall of Science and *Arts*), I suspect that the term is now intended to mean the useful and manufacturing arts. No one can deny that the word *Science* is properly associated with the *Art* of dyeing and calico-printing, the Society for the Encouragement of *Arts*, Manufactures, and Commerce, or the Dictionary of *Arts*, Manufactures, and Mines; but remove the final *s* in the last two instances, and the meaning becomes totally different.

Whatever may have been its original derivation and meaning, the word *Art* at present refers to two distinct functions. In one sense "Science and Art" is an incongruity, in the other sense it is a legitimate combination.

I am, &c. PUZZLED.

Mnemonic Nomenclature.

To the Editor of the CHEMICAL NEWS.

SIR,—Permit me to rectify a statement made by a correspondent on page 200, No. 285 of the CHEMICAL NEWS. Gmelin did not publish any new plan for a chemical nomenclature in the year 1827. At that time Laurent was still at school, and Dumas had not yet made the discoveries on which the doctrine of substitution was based. However, in the next "generation" (1848) a chapter on that subject appeared for the first time in the fourth edition of Gmelin's "Handbook of Chemistry." In the English translation of that work, this chapter, entitled "Suggestions for a New Chemical Nomenclature, particularly for Organic Compounds," occupies just four pages (vol. vii. pp. 149—153). The article, by its allusions to recently discovered compounds and new chemical reactions, bears internal evidence that it was written immediately prior to its publication in 1848. Long anterior to this date I had conceived the idea which was the germ of my own scheme. In 1850 I extended the system of counting so as to express the highest combinations. My first promulgation can be proved by the following statements by well-known scientists:—

"On consulting my diary I find that the first time you mentioned your new chemical nomenclature to me, in which you proposed to use vowels as numerals, and to distinguish the non-metallic elements by different consonant terminals, was on Saturday, May 13, 1848. . . . .

"This is no occasion on which to offer a criticism of your nomenclature, but I cannot refrain from adding my testimony to its wonderful adaptation to the simplest expression of the most complex chemical compounds.

"CHARLES A. JOY,
"Professor of Chemistry in Columbia College
and in the School of Mines, New York."

"For several years preceding 1846 Professor S. D. Tillman and I resided in the same town. I well remember his plan, then and there made, of a new chemical nomenclature, in which the name of a compound denoted its exact component parts. The number of equivalents was expressed by a vowel immediately preceding the last letter (m) in the names of all metals, as well as before the different consonants expressing non-metallic elements. . . . .

"EDWARD BAYARD, M.D.
"No. 6, West Fourteenth Street, New York."

The question of priority of conception will be deemed of minor importance by those who have carefully examined what has been done by Gmelin and by me. That Gmelin did not "fully elaborate" his scheme is evident from his own admissions. In the chapter alluded to (page 151, Watts's Translation, 1852) he says: "In working our the details of this nomenclature it would doubtless be found that many additions and corrections were necessary. . . . In a nomenclature for organic compounds something more is required than the names of elements and the expression of their numbers by vowels." This author gave new names to all the elements, yet failed to express any but the simplest facts of combination. After devising a very defective numerical system, in which the value of vowels depended on their position, he was compelled to coin new words for each nucleus having no reference to their composition, thus virtually abandoning the vowel plan. By scrutinising Gmelin's method any one who comprehends the requirements of a complete nomenclature will be convinced that the scheme cannot be used as a substitute for the notation. Similar objections may be made to Mansfield's method (see "Theory of Salts," London, 1865). This author shows that the use of the five vowels as numerals was of English origin, and was employed, although not in connexion with chemistry, in Dr. R. Gray's "Memoria Technica" (new edition, Oxford, 1831).

I claim for my scheme, which is adapted to Gerhardt's unitary system, and may properly be called "the unitary nomenclature," as its chief merit, simplicity of construction. Accepting the old names of the elements, I have so modified them that each begins with its old symbol, and ends with its new; the latter so generally correspond with the former that only seven new characters are introduced. With these materials and a more perfect numerical method than that employed by Gmelin, I have succeeded in representing, by a combination of letters and syllables, bodies of the most intricate structure. For the first time, systematic terms have been applied to radicals, so-called residues, and their numerous combinations. Every hydrocarbon has an appropriate symbolic appellation, and not only polymers but isomers have distinctive names. The only paper which I have yet published on the subject contains word-formulæ for more than *seven thousand compounds*.

Although the unitary nomenclature is commensurate with all possible atomic combinations, I do not claim that the new names would be preferable to a portion of the corresponding names now employed, nor do I entertain the hope that any part of the new scheme will be adopted until combinations of terms on the old plan become too cumbersome for common use.

I am, &c. SAMUEL D. TILLMAN.

American Institute, New York, May 11, 1867.

Manufacture of Sulphuric Acid.

To the Editor of the CHEMICAL NEWS.

SIR—In answer to the queries of "T. G. H., Lisbon," I beg to offer the following remarks:—

When pyrites is burnt, a considerable less quantity of sulphuric acid can be made with a given quantity of chamber space then when pure sulphur is employed, owing to the consumption of additional air in order to oxidise the iron, etc., in the pyrites; the nitrogen of the extra air thus employed occupies a portion of the chamber space, and thus renders the chamber relatively smaller. Also, to overcome the effect of the dilution of the gases, additional nitre must be employed. The quantity of sulphur which can be economically burnt with a given quantity of chamber space depends much on the mode adopted in working the chambers, on the size of condensing towers, etc., used. Usually there is a greater waste of sulphur when only one or two chambers are used than when several are worked together, arranged as "working" and "receiving" chambers. In Richardson and Watts's "Technological Dictionary," i. iii. p. 80, about 3000 cubic feet to 112 lbs. of sulphur per diem is given as an ordinary average quantity. This represents 1·672 cubic metre per kilogramme of sulphur per diem.

I am, however, acquainted with instances where a much larger proportion of sulphur has been regularly consumed than this. Thus, a single chamber, furnished with a coke condensing tower, burnt regularly 1 kilog. of sulphur (in the shape of pyrites, containing about 48 per cent. of sulphur) per diem to 1·047 cubic metre of chamber space; and at one time, when the manufacture was pushed to the utmost, only 0·726 cubic metres were allowed.

Several chambers worked together, on the English system, and furnished with good coke towers, averaged 1·080 cubic metre per kilog. of sulphur (as pyrites) per diem.

Allowing 1·200 cubic metre per kilogramme of pure sulphur per diem (representing about 2·1 kilos. of Huelva pyrites), a chamber of 29,000 cubic feet (English), or 821 cubic metres, should consume about 1437 kilogs. of Huelva pyrites daily. A kiln of the undermentioned dimensions will allow about 350 kilogs. or such pyrites per diem to be properly burnt. A larger quantity of pyrites may be passed through the kiln, but the burnt pyrites will frequently contain a considerable amount of unburnt sulphur. From 2 to 3 per cent. of sulphur is always left in the pyrites, so that four kilns of these dimensions would about suffice for the above chamber.

A convenient form of burner for Huelva pyrites is one measuring about 1·3 to 1·4 metre square at the level of the bottom of the charging door (*i. e.*, at the top of the mass of burning pyrites), and about 1·0 to 1·1 metre square at the level of the bars; between these levels a vertical distance of 0·6 to 0·7 metre is allowed. If deeper kilns be used, fluxing of the ore becomes a very probable occurrence. Larger or smaller kilns, with about the same relative areas, may be used.

A cast-iron pipe would, I think, be preferable to an earthenware one for conducting away the gases to the chamber, both on account of durability and the cooling of the gases. When pyrites is burnt, a thick sublimate is often formed in the pipe, materially diminishing its capacity. A tube of 0·5 metre internal diameter would suffice for the above kilns and chamber; but a larger one would be desirable, on account of this tendency to being blocked up.

A pipe of twenty-one metres length will hardly prevent fine dust of ferric oxide, etc., from being carried over into the chamber. For ordinary uses the presence of a little ferric sulphate, etc., in the acid produced is immaterial; but where concentrated acid is manufactured the presence of such bodies will often injuriously affect its sale. Arsenic is almost invariably present in acid made from pyrites. I am acquainted with an instance where the manufacture of sulphuric acid (rectified) from pyrites was given up, solely on account of the impossibility of selling the impure acid thus produced. It is, however, quite possible to obtain a colourless acid at 66° Baumé from Huelva pyrites.

Should "T. G. H." desire any further information, plans of burners, etc., I shall be happy to communicate with him.

I am, etc.,

Charles R. Wright, B.Sc.

St. Thomas's Hospital, Surrey, S., June 4.

Chemistry in Schools.

To the Editor of the Chemical News.

Sir,—Having now for three years made chemistry a regular and important part of my pupils' studies, I am able to speak most favorably of the general results of my experiment. At first I feared the boys would neglect their other work for the sake of this most fascinating subject, and that I should detect a falling off in their mathematics, or Latin, or history, or what not. My fear was entirely groundless. They have not learnt less of languages, but more of science. Boys who before had no idea of study for its own sake have been tempted to apply themselves, of their own accord, to chemistry, and, with the earnestness which this pursuit has put into them, have worked all the better at their other lessons. Of course they take more interest in the experiments than in the explanations. But even this characteristic of boys' nature has its good side. They are nor liable to value theories more than facts; and in course of time they learn to *ask* for explanations, and are not content till they get them. Chemistry teaches habits of careful observation, patience, caution, neat-handedness, and quickness. It stimulates ingenuity, and strengthens the faculty of generalisation. The other day I found that one of the boys had for months been colouring his maps with prussian blue of his own manufacture, having got it, by an obvious method, out of the red marl which abounds in this district. He dissolved the peroxide of iron with sulphuric acid, and precipitated his prussian blue with ferrocyanide of potassium. Without enlarging upon the topic of my letter further, I very strongly recommend those of my fellow-teachers who have not yet thoroughly tried the experiment, to introduce chemistry forthwith into their school-course; only it must be taught *well*—as accurately and as fully as the Latin or the mathematics. I am convinced that the most exact of the experimental sciences, lying at the basis of so many other departments of inquiry, must form an indispensable part of a judicious and philosophical scheme of education.

I am, etc., E. S.

Nottingham, June 6th, 1867.

The Tricks of Trade.

To the Editor of the Chemical News.

Sir,—Will you permit me to call public attention to a system which is undermining the chemical manufactures of the United Kingdom, and which, if not checked, will drive these important branches of industry, for which we possess such eminent natural facilities, more and more into foreign countries?

The evil to which I refer is that organized system of bribery and corruption prevailing in the sale of drugs and chemicals, such at least as are used in the cotton, woollen, and silk trades for dyeing, printing, bleaching, etc. Suppose, *e.g.*, that a traveller calls at a dyeworks and obtains an order. He immediately sends a message to the foreman who is to use the article, requesting an interview. The parties meet at some out-of-the-way public-house, and after a little general conversation over a glass of brandy, business begins. Says the traveller, "I've just seen your governor and got a trial order for a dozen bottles of 'double muriate,' and if you will give it a good character we will make it a snug thing for you." The foreman, putting on an air of complete indifference, asserts that he is very well satisfied with the article he has in use, but is, of course, not averse to anything really better. At length, after much bargaining and more brandy, it is agreed that, in consideration of a bribe of from 5s. to 10s. per carboy, the new article is to be reported better than the old. A couple of sovereigns are then handed to the foreman as a retaining fee, and the meeting terminates. It must be distinctly understood that if a traveller neglects thus to "make all right" with the foreman, his wares, how excellent soever, will, in most establishments, be condemned. If needful, a quantity of goods will be spoiled by some intentional neglect, and the blame will be laid on "that new lot of bottles."

If a traveller fails to obtain an order, he still seeks out the foreman, and, by dint of cash and promises, attempts to gain him over. "You are using Messrs. N. N's. wares? Well, you can say by opportunity that they have been falling off in quality, and that you have heard ours very highly spoken of. If you can get us in, you shall have so-and-so."

The amount thus given in bribery is enough to startle outsiders. I could point out a foreman dyer who demanded as the price of his good will 10s. per carboy on "scarlet finishing spirits," invoiced at 4d. per lb. As the carboys would average 130 lbs. net, this man's modest share of the plunder would amount to 23 per cent. On nitrate and nitro-sulphate of iron the "present quotations" are 1s. to 2s. 6d. per carboy, and on liquid ammonia 1s. to 2s. Solids and pastes, from obvious reasons, do not allow as much "tip" as liquids. Still the amount is in some cases considerable. On extract of indigo the fee averages 2s. 6d. per cwt. On cudbear and archil it is also heavy. I could name a foreman who received 14*l*. for using about 7½ tons of these articles. Other chemicals, such as oil of vitriol, soda-ash, and bleaching powder, are sold honestly when coming direct from the maker, though there are plenty of middlemen who sell these articles, of course duly adulterated, on the bribery system. I have never yet met with an authenticated case of "tip" being given on the aniline colours.

But to get in at an extensive dye or print works, some manufacturing chemists and drysalters will for a time go far beyond the tariff above given, even offering to hand over to the foreman who can manage the "job" the entire profits on all transactions for the first two or three months. A pattern-dyer, about to obtain a position in a first-rate establishment, holds a perfect *levee* of travellers and agents, and literally sells his future employer to the highest bidder. Nor is this all: the drysalter is expected to treat the foreman-dyer whenever they meet, to lend him a trap for an airing on Sundays, and to assist him if out of work or in trouble. Some firms give, yearly or quarterly, a dinner or supper to all foremen who patronise their wares. In one town there was established a so-called "dyers' club," ostensibly for discussing trade mysteries. It struck the public as suspicious that the traveller of one particular manufacturing chemist was unremitting in persuading dyers to attend the convivial meetings of the "club," and that this same chemist, or some representative of his, invariably occupied the chair on these occasions.

I must mention that, though foremen-dyers take a leading part in this system, yet the plunder is in many establishments shared by clerks, warehousemen, pattern-designers, and, in short, by any one who has contrived to gain a share of influence, and has opportunities of "ear-wigging" the master. Sometimes even one member of a firm is found accessible to bribery, and will, for so much per cask or per carboy, connive at the robbery of his partners and of himself.

Transactions of this nature sometimes come to light in an amusing manner. A young man who had represented an eminent drysaltery firm lately left them, and accepted a different employment in the same district. One day he received from his late principal a letter to this effect: — "We are forwarding a sample chest to Messrs. ———. As a large order is depending upon it, will you oblige by seeing their dyer, whom you know? Tell him that the chest is marked ———, and that if he will speak well of it we will make it a good thing for him. Please not to mention the matter to our present agent, as we are cutting the job too fine to allow him his commission." Another traveller offered the head dyer at a certain establishment 2s. 6d. per cwt. on a cask of extract of ———, for which he had just taken an order. The dyer, who had a share in the concern, at once mentioned this in the office; and when in due course the traveller called for the account, the amount, less 2s. 6d. per cwt., was paid him, with the intimation that any future visits would be useless.

Two makers, A. and B., had been in the habit of supplying "blue iron" to a certain dyeworks. A new head dyer who had been appointed declared himself unable to use A.'s, which he stated to be deficient in bloom. One day he sought up A., and said to him, "If you will give me 1s. 6d. per bottle, as B. does, I will give your blue iron a good character." A. not only refused, but told the man's employers, who, when B. called, informed him that they could only continue to do business with him on condition that he would supply them with the same quality of iron at 1s. 6d. per bottle less, to which, after a little bargaining, he consented.

The first result of the system is to encourage adulteration and other phases of commercial dishonesty. The object of the bribe-giver is to make the very poorest article which will pass muster. He therefore dilutes his liquid preparations with water as far as practicable, and, to keep up the specific gravity, adds matters more or less prejudicial. The weight of packages is often deficient. A dyer, bargaining with a traveller for an increase of "tip," has been known to say, "Empties are never tared at our shop, so you can write your tare three or four pounds lighter than it really is, keeping the gross right, and give me the price of what that will save you." The following ingenious scheme was practised for some time successfully by a manufacturing chemist: — The tops of his carboys were covered with several pounds of loose damp straw and rubbish, the tare being represented as lighter, and the net weight as heavier, than was the fact. The bottles being weighed, the gross was found correct, and they were passed on to the dye-house. In pouring out the contents of the bottles, this wet thatch fell off, and the empties, when returned to be tared, were found quite correct. A chemist has been known, among a dozen bottles of "red cotton spirits" and oxalo-chloride of tin, to send one or two bottles filled with water, and distinguished by a mark known to the dyer, who poured the contents down the sink and coolly fetched another bottle. The same dyer was in the habit of regularly wasting his mordants and colours in order that a fresh supply and a new bribe might be the result. He also, with the connivance of the gate-keeper, sent back bottles when only half empty. The chemist then filled them up and sold them afresh. By such means consumers are robbed of the money which is to corrupt their servants.

Another result of the system is the discouragement of invention and improvement. Success does not turn upon the question who can make preparations yielding at the cheapest rate the brightest, fastest, evenest, and solidest colours, but simply upon this—who can and will go farthest in the career of bribery and corruption?—a contest in which a Runge, a Hofmann, or a Perkin would inevitably be beaten by less scrupulous persons. You may make better mordants than ——, the old-established bribers. It is of no avail. The dyer will shake his head and say that he "can't get his colour" with your preparations. Nor is the case altered if you bring forward something entirely new. Your invention may save time and labour, and may give a better result, but the general question head dyers will ask is simply—How will it affect our perquisites? And unless this can be satisfactorily answered you will be "wet-blanketed" to your heart's content. Novelties like the aniline colours, of course, take the trade by storm; but many improvements, valuable if less striking, never get a fair trial. Thus invention is driven to seek elsewhere that scope which is denied at home.

Further, when a master dyer discovers how he is being robbed, he very naturally grows jealous, and, as far as possible, procures his requisites from foreign makers.

It may, perhaps, be objected that a dyer must get his colour, and, if so, that he cannot use really bad articles. I reply that a colour may be generally got in various ways, but that it is commercially essential to get it in the cheapest and quickest manner, and in the one which interferes least with the strength, durability, and suppleness of the fibre. There is also a wide margin between a colour which barely passes muster and one which is pronounced equal to the very best in the market. The bribe-loving dyer does not aim at excellence; his attention is sufficiently occupied with producing a passable result with the rubbish which his tempter puts in his hands.

The tinctorial trades of England are evidently not progressing as they ought. It is painful to see woollen mills running night and day to produce "sale-yarns"—*i. e.*, yarns which, instead of being dyed in this country, are exported uncoloured.

With your kind permission I will on a future occasion point out how the bribe-givers and bribe-takers may, to a great extent, be baffled. I am, etc., W.

[The statements in this letter are so well authenticated by the writer that we feel bound to give them insertion. At the same time we must express our conviction, in justice to many honourable firms, that such practices as above described are the exception rather than the rule.—Ed. C. N.]

Manufacture of the Bisulphide of Carbon.

To the Editor of the Chemical News.

Sir,—On looking over the article on the French Exhibition, in your last week's number, I was surprised to find that the writer had given M. Deiss, of Paris, the merit of being the first to introduce the manufacture of bisulphide of carbon on a large scale and at a low price for manufacturing purposes.

This is a mistake, and an injustice to myself, and for the sake of truth in the history of a new manufacture I beg to inform you that I took out my first patent in England, June 27, 1843, for the application of bisulphide of carbon as a solvent of india-rubber and other gums, and also as a solvent of phosphorus in connexion with some improvements in electro-metallurgy. Shortly before the date of this patent, all the sulphide of carbon I could procure either in England or Germany for my experiments was only six or seven ounces, costing sixty shillings per pound, and even for this I had to wait nearly six months. On applying to an eminent manufacturing chemist in London for help in the manufacture of bisulphide of carbon on a large scale, I was politely informed that I must be mad to expect that a hundredweight could be made, as the danger of preparing it would be fatal to any one making the attempt.

Being fully convinced of the very valuable properties of bisulphide of carbon for commercial purposes, I put up apparatus to prove that it could be produced in a large way and at a trifling cost, and completely succeeded.

In justice to a gentleman, Mr. Jesse Fisher, Madeley, Salop, whom I then employed to manufacture it on a large scale for Messrs. Elkington and Mason, who were interested in my patent, I would observe that under my instruction he erected the necessary apparatus, and in the year 1844 made many tons weight at a cost of one shilling per pound, and very soon afterwards he was able to produce it at threepence per pound; and that gentleman has continued the manufacture in England ever since. My object in furnishing this information is to show that, long before M. Deiss gave his attention to the subject, I had succeeded in making a large commercial manufacture of bisulphide of carbon, and I was also the first to introduce it for manufacturing purposes. And, in fact, before M. Deiss commenced his operations in the manufacture of this article it had been made by the ton at threepence per pound, and it was not used at all in France until the introduction of my patent for improvements in treating india-rubber in that country; from which you will see that it was in the year 1844 that I made it a success, and not, as stated in the article in the Chemical News, 1848.

I am, etc., Alexander Parkes.

Birmingham, May 28.

Manufacture of Sulphuric Acid.

To the Editor of the Chemical News.

Sir,—In No. 392 of your journal I notice a letter on this subject. Among other matters the writer states that "it is quite possible to obtain a colourless acid at 66° Beaumé from Huelva pyrites." I was not aware that there was any difficulty in preparing an acid, colourless and pretty pure, from this class of pyrites. With regard to the fixing of the pyrites, I can say that carelessness has as much to do with this irregularity as wrong construction of the burners. A want of proper attention on the part of the burner-men in breaking up the sulphur ore, and managing a regular and sufficient supply of air, is a most frequent cause of fluxing; in ninety-nine cases out of a hundred this is the sole cause. Then we have the complaint of the small quantity of acid got from chambers which have been constructed to produce a far larger amount than is ever obtained from them; in many cases the cause of this proceeds from the too slow combustion of the sulphur ore; a greater part of the pyrites may be "dead out" or only half ignited, generally proceeding from the want of a proper supply of air.

Again, the steam may not be admitted into the chamber in a satisfactory way. This matter is much overlooked. Some makers admit the steam at stated intervals. Now this is wrong; the admittance of steam should be continuous and at a proper pressure. We often hear of the acid doing serious damage to the platinum stills, and the cause is often overlooked for a length of time; this is more particularly the case where the proprietor has no scientific supervision. At last it is discovered that the cause of the damage proceeds from the presence of oxide of nitrogen in the acid. It is well known that acid so contaminated has the property of attacking platinum. The most important part of the process is frequently left in the hands of the burner-men, and left entirely to them as to how the manufacture shall be conducted. In some cases this plan may work well, when the men happen to be intelligent; but in many cases the men are lamentably ignorant. This mostly arises from the fact that no trouble is taken by the manager or chemist to explain to the men in simple language the various processes connected with their work. This is seldom the case; the men go mechanically about their work, and so long as things happen to go right no further interest is taken, but let anything out of their ordinary course occur, and the men are at sea.

However unimportant what I have said may appear, I have always found it to my interest to have the men as well informed as possible. Carelessness and inattention to trivial matters often lead to the downfall of many operations in manufacturing chemistry.

In your "Suggestion to Manufacturers and Inventors" you make a very good remark respecting the difficulties which often beset the manufacturer, and which might easily be overcome by a short investigation by some competent chemist, "and in many cases a difficulty which appears insuperable to the manufacturer would prove a mere bagatelle to the chemist." Your ideas coincide with mine, but I know many manufacturers who object to a scientific man having access to their works. I can say, however, that such supervision is much needed by them.

I am, etc. J. H. Swindells.

Cure for Dry Rot in Houses.

To the Editor of the Chemical News.

Sir,—It may be of interest to many of your readers, whose houses are infested with dry rot, to learn that a perfect cure, or rather a way of preventing it, has been found out in the alkali works at Saaran, in Silesia. The dry rot is caused by the spores of a fungus (*Merulius lacrymans*), which may be carried away by currents of air, but are mostly contained in the soil. If any soil containing them be used for filling the spaces between the joists and boarding of a chamber-floor, the appearance of dry rot in the house need not create any surprise. A little of such earthy matter may easily be mixed among the sand or slag, if such is used for filling those spaces, or even among the sand which forms part of the mortar. Of course dry rot will not set in if the timber is kept completely dry; but it is well known that this condition is often not easily achieved. A radical remedy against dry rot is, however, found, if the space underneath the flooring boards be filled with a mass capable of destroying vegetable life without doing any injury to the timber or brickwork. No doubt many such compositions might be found, but the builders would be deterred by any considerable expense from using them. Now, on the Saaran alkali works it has been observed (as the manager, Mr. Junker, reports in the *Breslauer Gewerbeblatt*) that tank-waste, that great nuisance of alkali works, is an excellent remedy against dry rot. If some of it is used along with the rubbish for filling the spaces between the joists, and if the whole is beaten down into a mass, it hardens very well, like ordinary tank-waste floors, and it never allows any dry rot to spring up. It makes no difference whether the air has access or not; there is also no smell whatever exhaled. Besides many other striking illustrations of the efficacy of tank-waste in this respect, Mr. Junker mentions a case where two adjoining souterrains had been boarded, the one with, the other (by mistake) without, the application of tank-waste. The latter room was at once infested with dry rot; the former remained quite sound. The boards of the infected room were then taken up again, and tank-waste was applied; since that time (two years and a half) no dry rot whatever has set in, and the decay of the boards, half-rotten as these had already become, was stopped altogether.

None of your readers need be told that tank-waste may be had at all alkali works for the carting away.

I am, etc. G. Lunge.

Test for Cobalt.

To the Editor of the Chemical News.

Sir,—Having tried some experiments on the new test for cobalt (viz., the production of a deep red coloration on the addition of tartaric acid, excess of ammonia, and ferricyanide of potassium), I found that not only was the coloration produced when tartaric or oxalic acid had been added, but with any other acid (as many as I tried) or salt of ammonia, provided that the acid (or salt), ammonia, and ferricyanide were first mixed and then added to the solution of cobalt.

For instance, the coloration is developed quite as well by the addition of a mixture of chloride of ammonium, ammonia, and ferricyanide, as in the method by tartaric acid. The acids tried were hydrochloric, nitric, sulphuric, carbonic, chromic, and acetic. Probably these experiments have been already tried, but, not having seen them mentioned, I thought it best to place them on record.

I am, etc. Tyro.

Tricks of Trade.

To the Editor of the Chemical News.

Sir,—Drugs and chemicals are not the only things that absorb so much "bribing;" here is a sample of one style, to hand this morning:—

"Messrs. G——— and Co., D**** Street.—The *employés* in the above firm most respectfully beg to intimate that they intend celebrating their second annual dinner on Saturday, July 27, 1867. The favour of your subscription in aid of the above will be most thankfully received. Yours respectfully, for the *employés*, A. D**. N.B.—Post-Office Orders to be made payable at Gray's Inn Road."

Persistent neglect of all such dishonesty has lost the writer many a customer's trade. But what are we to expect when masters are so ignorant of their own businesses as is generally the case? Having no judgment of their own, nor capability of testing for themselves and proving, they are afraid to unsettle this foreman or that workman. I shall be glad to hear your correspondent's solution of the problem, *how* to neutralise it; but when competition is strong, British honour is a myth.

I am, etc. T. C.

Manufacture of Bisulphide of Carbon.

To the Editor of the Chemical News.

Sir,—Mr. Parkes errs in conveying the impression that my apparatus for the manufacture of bisulphide of carbon was erected under his instructions. The only assistance he rendered me was in directing my attention to the article in Mitscherlich's "Practical and Experimental Chemistry," translated by Dr. Hammock in 1838 (pp. 209–12), which upon examination, you will find, was not calculated to aid me much; and Mr. Parkes' first visit to my works was in 1849, some years after I had been engaged in the manufacture.

I am, etc. Jesse Fisher.

Chemical Works, Ironbridge, Salop, June 24.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Colours from Coal-tar. (C=6).—De Laire, Girard, and Chapoteaut. If, in preparing violaniline (3 molecules of aniline conjoined with elimination of H_6), aniline containing toluidine be used, the product is contaminated with a small quantity of rosaniline, and a larger proportion of mauvaniline—

$$\left.\begin{matrix} C_{12}H_4,H \\ C_{12}H_4,H \\ C_{14}H_4,H \end{matrix}\right\} N_3,HO,$$

a base possessing remarkable tinctorial properties. Its formula is substantiated—1st. By its formation by appropriate oxidation of a mixture of aniline and toluidine containing a greater proportion of the former. 2nd. By simultanous formation of water. 3rd. By the replacement in its molecule of H_3 by methyl, ethyl, phenyl. 4th. By its decomposition on distillation into the primary and secondary monamines of the phenylic and toluylic radicals. It is derived from two molecules of aniline and one molecule of toluidine, H_6 being eliminated; it is crystallisable; retains HO even after several hours' exposure to 120—130°, but loses it at a higher temperature; it is soluble in ether, benzol, and alcohol; insoluble in cold, sparingly so in boiling water; it forms crystallisable salts with acids; the acetate and chlorhydrate are especially fine bodies; the salts are slightly soluble in cold water; rather soluble in boiling water. Triphenylomauvaniline is obtained by acting upon mauvaniline with aniline; it is a crystallisable base, soluble in ether and alcohol, insoluble in water; its salts form splendid blue dyes.

Violaniline, mauvaniline, rosaniline, and chrysotoluidine (derived from the conjunction of three molecules of toluidine, H_6 being eliminated) are the first four consecutive terms of a series having a common difference C_2H_2.—*Comptes R.* lxiv. 416.)

Retene: its Constitution (C= 6).—M. Berthelot. Retene $C_{36}H_{18}$ is distinguishable from naphthalene, which it resembles in aspect by its having no odour, by its lesser solubility in alcohol, and by its melting at 95°; it boils at at about 400°; the vapour, mixed with hydrogen and passed through a red-hot tube, decomposes, producing large quantities of anthracene, carbon, acetylene, and some gaseous hydrocarbons, one of which is absorbed by monohydrated sulphuric acid. Yielding, under these conditions, anthracene, from which it differs by $4C_2H_2$, it cannot be derived from benzol, although its formula is triple that of benzol. but it might be derived from benzol and a hydrocarbon such as ethylene or formene, capable of supplying the acetylene necessary for the production of anthracene, its lower homologue. Attempts to obtain it from cumol in a reaction similar to that which gives anthracene from toluol have not been successful. The first members of the homologous series commencing with anthracene, and including retene, will probably be found among the solid hydrocarbons which crystallise immediately after naphthalene in the heavy oil of coal-tar.—(*Bull. Soc. Chim. Paris*, 1867, 231.)

Xylol, Chloro derivatives of (C=12).—C. Lauth and E. Grimaux. (Xylol distilling entirely between 137° and 139°) vapour and chlorine gave a liquid from which a fraction collected between 190—195° precipitated cold argentic nitrate solution: boiled with argentic acetate, a liquid of agreeable odour, probably tolylic acetate was formed; boiled with plumbic nitrate solution, a liquid having an odour resembling bitter almond oil, combining with sodic disulphite, and boiling at 200°, was produced, evidently C_8H_8O tolylic aldehyde. Therefore, in the first-mentioned reaction a change occurs analogous to that by which benzylic chloride is produced from toluol, and the chlorxylol obtained should be represented by

$$C_6H_4\left\{\begin{matrix} CH_2Cl \\ CH_3 \end{matrix}\right.$$

The fractions distilling between 230—260° contained $C_8H_8Cl_2$, a crystalline body, but in smaller quantity than was necessary for the study of its reactions; it melts at 100°. It is proposed to extend this reaction to trimethylphenyl, cumol from coal-tar, the alcohol $C_9H_{12}O$ being at present unknown.—(*Bull. Soc. Chim. Paris*, 1867, 233.)

Benzolsulphurous Acid (C = 12).—R. Otto and H Ostrop. Benzolsulphurous chloride, $C_6H_5ClSO_2$, most carefully dried, was diluted with ether perfectly free from alcohol and water; sodium amalgam was added by small portions till a sample of the fluid, after expulsion of the ether, dissolved in water; the ether was then expelled, and a small quantity of water was added; the aqueous solution was separated from an oily body and mixed with chlorhydric acid; the crystals which formed were recrystallised from hot water, and about two-thirds the theoretical quantity of benzolsulphurous acid was obtained. Its properties were the same as described by its discoverer, Kalle, who made it from zincic ethide and benzolsulphurous chloride. With fuming nitric acid benzolsulphurous acid gave $C_{18}H_{16}N_2S_3O_6$, for the unravelling of the constitution of which material was wanting; nitrobenzolsulphuric acid $C_6H_5(NO_2)SO_3$, was also formed. With bromine, benzolsulphurous bromide was produced, C_6H_5,SO_2,Br, and not brombenzolsulphurous acid, C_6H_4Br,SO_2,H, for ammonia gives with it an amide, and not ammonic brombenzolsulphite. With phosphoric pentachloride, benzolsulphurous chloride, and a body probably $\Theta_{12}H_{10}S_2O_3$, separated from the former by dilute solution of potash, were obtained. The oily body formed in the first reaction, and toluol- and xylol-sulphurous acids, will form the subjects of future communications.—(*Ann. Chem. Pharm.* cxli. 365.)

Cyanin (C = 12).—Dr. G. Nadler and Dr. V. Merz. The cyanin, or chinoline blue, which forms the subject of this paper, was prepared from tolerably pure chinoline, and was, therefore, an amylchinoline derivative. Chinoline blue, or iodocyanin, $C_{28}H_{35}N_2I$, is almost insoluble in ether and cold water, rather soluble in hot water, sparingly so in cold alcohol, and very soluble in hot alcohol; the green crystals melt and lose water at 100°; their solution in alcoholic solution of nitric acid is precipitated by argentic nitrate. Iodocyanin is capable of uniting with one or two molecules of acids; its solution in chlorhydric acid, if allowed to evaporate spontaneously in the presence of lime, deposits colourless crystals, $C_{28}H_{35}NI_2H2Cl$, which lose HCl at 90—100°. A warm alcoholic solution of iodocyanin digested with fresh argentic oxide gave cyanin $C_{28}H_{36}N_2O$. A chlorhydric acid solution of cyanin precipitated by ammonia, or an alcoholic solution of iodocyanin digested with argentic chloride, gives chlorocyanin, $C_{28}H_{35}N_2Cl$, easily soluble in alcohol and hot water, sparingly so in ether and cold water, combining with acids to form colourless compounds. Nitrato-cyanin was prepared by precipitating an alcoholic solution of iodocyanin, acidulated with nitric acid, with argentic nitrate; it is slightly soluble in ether and cold water, easily so in alcohol; its formula is

$$\left.\begin{matrix}C_{28}H_{35}N_2\\ NO_2\end{matrix}\right\}O;$$

it combines with acids to form colourless bodies; treated with ammonic sulphide at 100°, $C_{56}H_{68}N_4S_2O_2$ was obtained. Iodocyanin, heated with concentrated sulphuric acid, gave sulphatocyanin—

$$\left.\begin{matrix}2C_{28}H_{35}N_2\\ SO_2\end{matrix}\right\}O_2,$$

which, air-dried, is a light brown body, which decomposes, without melting, at 120°. From it other similar bodies, such as oxalocyanin.

$$\left.\begin{matrix}2C_{28}H_{35}N_2\\ C_2O_2\end{matrix}\right\}O_2,$$

are obtainable.

It appears from the above that cyanin is capable of forming with acids three kinds of bodies—the monacid bodies are intensely coloured, the triacid compounds are colourless and easily decomposed, giving rise to diacid compounds. All the coloured compounds are unstable in sunlight.—(*Journ. prakt. Chem.* c. 129.)

Alizarin.—C. Koechlin. The colouring matter from madder, after sublimation or exposure to 280°, no longer gives the tints sought by dyers: a yellow tint is wanting, in searching for which the author is engaged with Schützenberger. —(*Bull. Soc. Chim. Paris*, 1867, 235.)

Valerylene, Polymers of (C = 12).—E. Reboul. Concentrated sulphuric acid acts violently on valerylene; no conjugated acid is formed. A fraction of the product between 175—177° was divalerylenic hydrate, $2C_5H_8,H_2O$. The fraction between 265—275°, sp. gr. 0·862, at 15°, was trivalerylene, $(C_5H_8)_3$. The distillate between 280—350°, in which interval the thermometer rises continuously, as also the residue, which, on cooling, solidified to a semi-transparent mass, is a mixture of polymers of different degrees of condensation. Sulphuric acid diluted with one or one-third volume of water produces the same results, but more slowly, and consequently with less violence.—(*Comptes R.* lxiv. 419.)

Oxalohydroxamic Acid (C=12).—H. Lossen. This is one of two acid bodies formed by the action of hydroxylamine on ethylic oxalate; it is very difficultly soluble in cold water, but crystallises from boiling water; it explodes at 105°; dried over sulphuric acid it contains $C_2H_4N_2O_4$, which formula, however, may need to be tripled. Its salts are generally insoluble, or sparingly soluble, in water, and explode if heated to 130° or 180°, or if put into concentrated sulphuric acid. The constitution of the acid is probably expressed by

$$\left.\begin{matrix}C_2O_2\\ (HO)_2\\ H_2\end{matrix}\right\}N_2$$

(*Zeitschr. Chem.*, N. F., iii. 129.)

Sarcolactic Acid.—O. Schultzen. The urine of men or animals that have been poisoned by phosphorus, when the poisoning has reached the stage of colouring the skin, contains large quantities of this acid. To extract it the urine was evaporated to syrupy consistence, the alcoholic extract of the syrup was evaporated, the residue was treated with sulphuric acid and ether, the ether was decanted, and the substance left on its evaporation was purified by a small quantity of plumbic acetate freed from lead by sulphydric acid, and from acetic acid by evaporation; sarcolactic acid remained, which was identified by analysis of the zincic, cupric, and calcic salts. (*Zeitschr. Chem.* N. F., iii. 138.)

Bichlorsulphobenzide (C = 12).—R. Otto. This body—

$$\left.\begin{matrix}C_6H_4Cl\\ C_6H_4Cl\end{matrix}\right\}SO_2$$

is easily obtained by the action of chlorobenzol on sulphuric anhydride. It is insoluble in water, and crystallises from hot alcohol in long white needles, melting at 140—141°.—(*Zeitschr. Chem.*, N. F., iii. 143.)

Chlorbenzolsulphuric Acid (C=12).—R. Otto. This acid is a by-product in the preparation or bichlorsulphobenzide. It is obtainable in long white asbestoslike deliquescent needles, fusible in the water oven, easily soluble in water and alcohol, insoluble in ether and benzol. It is monobasic—

$$\left.\begin{matrix}C_6H_4Cl\\ SO_2\\ H\end{matrix}\right\}O.$$

Its salts are mostly soluble in water, and may be heated to 200° without decomposition. The sodic, potassic, calcic, baric, plumbic, cupric, and ethylic salts are described.

The chloride

$$\left.\begin{matrix}C_6H_4ClSO_2\\ Cl\end{matrix}\right\}$$

is easily obtained by acting upon sodic chlorbenzolsulphate with phosphoric pentachloride. It is soluble in ether, benzol, and alcohol; insoluble in water. It forms magnificent four-sided rhombic tables, often of considerable dimensions. It melts at 50—51°. With alcoholic solution of ammonia, sulphochlorbenzolamide is formed,

$$\left.\begin{matrix}C_6H_4ClSO_2\\ H_2\end{matrix}\right\}N,$$

crystallising from water in four-sided rhombic pillars of large size. It melts at 143—144°. By acting on chlorbenzolsulphuric chloride with zinc and sulphuric acid, chlorphenylphydrate is obtained,

$$\left.\begin{matrix}C_6H_4Cl\\ H\end{matrix}\right\}S,$$

which forms superb crystals, melting at 53—54°, distilling undecomposed, insoluble in water, soluble in ether and alcohol. It combines with mercuric chloride to form a compound insoluble in boiling water or alcohol, and gives with nitric acid chlorphenylic sulphide,

$$\left.\begin{matrix} C_6H_4Cl \\ C_6H_4Cl \end{matrix}\right\} S_2,$$

insoluble in water, easily soluble in hot alcohol, ether, or benzol, melting at 71°, and distilling undecomposed.

Chlorbenzolsulphurous acid results from chlorbenzolsulphuric chloride under the influence of sodium amalgam. It crystallises in small rhombic needles, easily soluble in hot water and alcohol, melting at 88—90°. The sodic, calcic, plumbic, and ethylic salts are described. Its formula is

$$\left.\begin{matrix} C_6H_4Cl \\ SO \\ H \end{matrix}\right\} O.$$

—(*Zeitschr. Chem.*, N. F., iii. 144.)

Organic Acids, a New Series of (C=12).—P. Greiss. Diazobenzoic perbromide (*Ann. Chem. Pharm.* cxxxv. 121), in solution of ammonia, decomposes with formation of $C_7H_5N_3O_2$, easily soluble in alcohol and ether, difficultly so in boiling, insoluble in cold water, melting at about 160°; it forms definite salts. The argentic salt is a white amorphous precipitate, $C_7H_4AgN_3O_2$. Analogous acids are formed by the action of ammonia on diazodracylic and diazosalylic perbromides. Diazoanissic and diazobippuric perbromides react in a similar manner. The reaction is therefore general. —(*Zeitschr. Chem.*, N. F., iii. 164.)

Ethyl- and Diethyl-benzol, products of Oxidation of (C=12.)—R. Fittig and J. König. Ethylbenzol is easily oxidised by dilute nitric acid, benzoic acid with traces of a nitro-acid being produced. Monobromethylbenzol gave by oxidation bromdracylic acid, identical with that obtained by Hubner and Philipp from bromtoluol. Diethylbenzol, treated with potassic dichromate and sulphuric acid, gave terephthalic acid, but, if oxidised with dilute nitric acid, an acid isomeric with xylylic acid is produced, and which may be called ethylbenzoic acid,

$$C_6H_4\left\{\begin{matrix} CO_2H \\ C_2H_5. \end{matrix}\right.$$

It crystallises from water or alcohol, and melts at about 110°. The baric, calcic, argentic, and cupric salts were analysed. This acid differs from all others of similar constitution. It may be regarded as bromdracylic acid, in which Br is replaced by ethyl; and it will perhaps be identical with an acid which Kekulé hopes to obtain by the action of bromethylbenzol on sodium and carbonic dioxide. The production of bromdracylic acid above mentioned proves that in bromethylbenzol the same H atom in the benzol residue is replaced by bromine, as is the case in bromtoluol.—(*Zeitschr. Chem.*, N. F., iii. 167.)

Opium, Alkaloids of: their Separation.—M. Kubly. The substance to be examined is extracted with benzol; narcotine, papaverine, thebaine, and codeine, are dissolved. Amylic alcohol dissolves morphine from the residue, and alcohol will extract narceine, if present in what is left undissolved by the two former solvents. To separate the four alkaloids soluble in benzol, cold amylic alcohol is used, which dissolves codeine; very dilute acetic acid will then extract papaverine and thebaine from the narcotine which remains. Finally, thebaine is precipitated from the sulphuric acid solution of papaverine and thebaine by bismuthic iodide in potassic iodide solution, papaverine remaining in solution.—(*Pharm. Journ. Russ.* Nov. 1866, 457.)

Cleaning Glass.—A method of cleaning glass, which may be useful where other methods fail, is given in the appendix to the second edition of Major Russell's "Tannin Process," published by Robert Hardwicke, Piccadilly. Dilute the ordinary hydrofluoric acid sold in gutta-percha bottles, with four or five parts of water, drop it on a cotton rubber (not on the glass), and rub well over, afterwards washing till the acid is removed. The action is the same as that of sulphuric acid when used for cleaning copper; a little of the glass is dissolved off and a fresh surface exposed. The solution of the acid in water does not leave a dead surface on the glass, as the vapour would; if a strong solution is left long enough to produce a visible depression, the part affected will be quite bright. This method is recommended in some cases for cleaning photographic plates, but we should think it might also be useful in cleaning the insides of bottles, flasks, etc., which have got stained through use.

A Quinine Famine.—The following is an extract from a letter from Mr. Colville Barclay, President of Poor Relief Committee of the Island of Mauritius: "The mortality from the effects of fever just now is from 180 to 200 every day throughout the island. All the quinine in the place is finished, and half a dozen bottles received from Reunion last week were sold at 135 dollars the ounce (27*l.* 10*s.*). The doctors are using arsenic as a substitute. The Government has sent home for 30 lbs. of quinine, as well as to Ceylon and the Cape for all that can be obtained."

Cantharidin.—Professor Dragendorff has found in cantharides a volatile body which acts on the organism in a similar manner to cantharidin. Freshly powdered cantharides are moistened with water and distilled; the portion going over below and at 100° C., which has an acid reaction, contains the new body.—(*Pharm. Zeitschr. f. Russl.*, Jan. 1867, i.)

Borates.—F. P. le Roux. Equal equivalents of calcined magnesia and boric anhydride, heated to whiteness, melt readily together, forming a slightly green, strong, and light glass. Rapid cooling is necessary to obtain it amorphous and transparent. Three equivalents of boric anhydride and one equivalent of suboxide of copper, melted together, and poured on an iron plate, form a glass, the surface of which has a different colour from the interior.

Other borates behave in a similar manner; most of them form glasses of different colours, according to whether, after melting, they are cooled slowly or rapidly.—(*Comptes R.* lxiv. 26.)

Electrolysis of Alkalic Sulphides.—H. Buff. In an electrolyte under the action of an electric current, elements, or groups of elements, travel in opposite directions, carrying an equal amount of electricity of opposite nature; they are electric-equivalent. Constituents not taking part in this locomotion do not contribute to the conduction of the electric current.

From his experiments with alkalic sulphides, the author concludes that the decomposition of the various mono- or poly-sulphides of potassium or sodium always takes place in this manner, that the metals travel towards the one electrode and all the sulphur towards the other, or that a group of, for instance, five atoms of potassic pentasulphide is electric-equivalent to one atom of potassic monosulphide. —(*Ann. Chem. Pharm.* Supplem. iv. 257.)

Niobium and Tantalum, Chloro- and Chloro-oxygen Compounds of.—H. Sainte-Claire Deville and L. Troost (O=16). The vapour densities of the volatile niobic chlorides and oxychlorides agree with Marignac's formulæ $NbCl_5$ and $NbOCl_3$. The presence of oxygen in the oxychloride may also be proved synthetically. If $NbCl_5$ (melting at 194° C., boiling at 240° C.) in a state of vapour is repeatedly driven over red-hot niobic anhydride (in a current of carbonic anhydride), it is converted into a white non-fusible body, volatile at about 400° C., having all the properties of the oxychloride.

$TaCl_5$ and tantalic anhydride, under the same conditions, do not act upon each other. The chloride obtained from pure tantalic anhydride, prepared according to Marignac's method, is crystallisable, melts at 211·3° C., and boils at 241·6°. It has a slight yellow colour, and decomposes slowly when exposed to air. The density of its vapour was found to be 12·8; theory requires 12·5 (Ta = 182).—(*Comptes R.* lxiv. 294.)

Rosaniline, Derivatives of.—H. Schiff (C = 12). Sulphite of rosaniline, dissolved in aqueous sulphurous acid (a yellow solution, containing leucaniline salt and polysulphite of rosaniline), shaken with a few drops of an aldehyde, evolves sulphurous acid, and a violet crystalline precipitate is gradually formed. Rosaniline salts treated in this manner with oil of bitter almonds, œnanthol, or valeric aldehyde, gives rise to the formation of the new bases

$$N_3 \left\{ \begin{array}{l} C_{20}H_{16} \\ C\ H_6 \\ H \end{array} \right. \qquad N_3 \left\{ \begin{array}{l} C_{20}H_{16} \\ C_7H_{14} \\ H \end{array} \right. \qquad N_3 \left\{ \begin{array}{l} C_{20}H_{16} \\ C_5H_{10} \\ H \end{array} \right.$$

Benzyliden-rosaniline. Œnanthyliden-rosaniline. Valeryliden-rosaniline.

The salts of these bases contain one equivalent of acid. The typical hydrogen may be replaced by ethyl. They are insoluble in ether, water, or dilute acids; soluble in alcohol, with a violet blue colour.

The author believes that the blue and violet dyes obtained by the action of the bromides of terebene and ethylene upon rosaniline have a similar constitution to the bases described. —(*Comptes R.*, lxiv. 182.)

Triamidophenol and Amidodiimidophenol.—C. Heintzel (C=12). The product of the reduction of picric acid with tin and chlorhydric acid the author finds to be hydrochlorate of triamidophenol, protochloride of tin $C_6H_2(HO)(NH_2)_3(HCl)_3(SnCl_2)$, and not, as stated by Beilstein, $C_6H_3(NH_2)_3(HCl)_3(SnCl_2)$, hydrochlorate of picrammonium, protochloride of tin. The body is soluble in water, alcohol, and ether, and is obtained in white crystals by precipitating its saturated aqueous solution with chlorhydric acid. Sulphuretted hydrogen decomposes it, and forms hydrochlorate of triamidophenol, $C_6H_2(HO)(NH_2)_3(HCl)_3$, easily soluble in water, and obtained from its solution in white crystals on adding chlorhydric acid. It is less soluble in alcohol and ether.

Hydriodic acid reduces picric acid to hydriodate of triamidophenol $C_6H_2(HO)(NH_2)_3(HI)_3$, and not, as Lautemann stated, to hydriodate of triamidobenzol, or, as he called it, picrammonic iodide, $C_6H_3(NH_2)_3(HI)_3$.

Triamidophenol cannot be separated from its salts without decomposition.

Ferric chloride acting on the hydrochlorate produces the hydrochlorate of amidodiimidophenol,

$$C_6H_2(HO)(NH_2)(N_2H_2).HCl.$$

It dissolves easily in water, with a beautiful blue colour, is sparingly soluble in alcohol, insoluble in ether, and crystallises in dark yellow needles. The base cannot be separated from its salts without decomposition. Digestion with dilute chlorhydric or sulphuric acid converts this body into the hydrochlorate of a new base, the probable formula of which is $C_6H_2(HO)(NH_2)(NH)(HO).HCl$. That is hydrochlorate of amidoimidohydroxylphenol, soluble in water and alcohol.

Another new base is obtained from hydrochlorate of amidodiimidophenol on reduction with tin or zinc and chlorhydric acid of its aqueous, or, with sodium amalgam, of its acid solution. It can be isolated from its salts by means of an alkali. It crystallises in white needles, dissolves readily in water, sparingly in alcohol.

The author here corrects his former statement, published in a preliminary communication (*Zeitschr. Chem.* 1866, 211), that by this reduction the hydrochlorate of triamidophenol was regenerated.—(*Journ. prakt. Chem.* c. 193.)

Methods of Reduction, new Application of.—Berthelot (C=12). Bromide of ethylene with water and potassic iodide, heated in sealed tubes for ten hours, is first converted into iodide of ethylene, and this is decomposed again according to the following equation:—

$$7\,C_2H_4I_2 + 4\,H_2O = 6\,C_2H_6 + 2\,CO_2 + 7\,I_2.$$

The reaction can only be explained by the supposition of a temporary formation of hydriodic acid. This caused the author to investigate the action of a strong aqueous solution of this acid on various substances at a high temperature (275° C.) in sealed tubes. Under these conditions hydrocarbons of the marsh-gas series were obtained in most cases.

Marsh gas was produced in this way from methylic formate, besides carbonic oxide and water, resulting from the decomposition of the formic acid.

Ethylic hydride resulted from the reduction of chloride, bromide, and iodide of ethylene, bihydriodate of acetylene, ethylic iodide, carbonic sesquichloride, ethylene, acetylene, alcohol, aldehyde, acetic and tartronic acid. The last-named body also gave rise to the formation of carbonic anhydride, evidently in consequence of its having split up originally into carbonic anhydride and acetic acid, the latter only giving ethylic hydride.

Propylic hydride was obtained from allylic iodide, glycerin, and acetone.

Butylic hydride from butyric acid and succinic acid. The gaseous hydrocarbons in most cases contained an admixture of hydrogen, derived, no doubt, from spontaneous decomposition of the hydriodic acid used in the experiments. From oxalic acid no carburetted hydrogen could be obtained, only carbonic oxide and carbonic acid, from formic acid carbonic oxide only (*Bull. Soc. Chem.* 7, 53).

Benzol and Phenol, Sulpho-derivatives of, (C=12).—A. Kekulé. Vogt's benzylmercaptan may be prepared by substituting sulphur for oxygen in phenol. Phosphoric sulphide and phenol are heated together in a retort, and the mixture distilled. The principal product of the reaction is thiophenol C_6H_5SH, identical with the benzylmercaptan of Vogt, obtained by the action of zinc and sulphuric acid on benzolsulphochloride. The other bodies formed are benzol, sulphide of benzol, and liquids of a high boiling point, probably phenylethers of sulphophosphoric acid. The sulphide of benzol thus obtained has been found identical with the sulphide obtained by Stenhouse from sodic benzolsulphate. The substance produced by oxidising sulphide of benzol, and called by this chemist sulphobenzolen, the author declares to be identical with sulphoxide of benzol.

Benzylmercaptan may be converted into sulphide of benzol by exposing one of its metal compounds to dry distillation. The decomposition takes place according to the following equation:—

$$2(C_6H_5SM) = (C_6H_5)_2S + M_2S.$$

Experiments in progress seem to show that thiophenol may be converted into benzol by losing its sulphur, or into phenol by exchanging it for oxygen.—(*Zeitschr. Chem.*, N F., iii. 193.)

Thiacetic Acid from Acetic acid Phenol (C=12).—A. Kekulé. Phenol is still very generally believed to be in every respect analogous to the monatomic alcohols. It may now, however, be taken as certain that the so-called phenylic chloride, iodide, etc., are identical with the corresponding substitution compounds of benzol, and that the phenyl therein is incapable of being transferred to other compounds. According to the old view, acetic acid phenol acted upon by potassic sulphhydrate ought to give potassic acetate and thiophenol:—

$$\left.\begin{array}{l} C_6H_5O \\ C_2H_3 \end{array}\right\} O + \left.\begin{array}{l} K \\ H \end{array}\right\} S = \left.\begin{array}{l} C_6H_5 \\ H \end{array}\right\} S + \left.\begin{array}{l} C_2H_3O \\ K \end{array}\right\} O$$

The reaction, however, takes place in a different manner; phenol is formed and potassic thiacetate:—

$$\left.\begin{array}{l} C_6H_5 \\ C_2H_3O \end{array}\right\} O + \left.\begin{array}{l} K \\ H \end{array}\right\} S = \left.\begin{array}{l} C_6H_5 \\ H \end{array}\right\} O + \left.\begin{array}{l} C_2H_3O \\ K \end{array}\right\} S$$

Showing that it is not phenyl and the metal of the sulphhydrate which exchange their places, but hydrogen and acetyl, and that acetic acid phenol should not be viewed as phenylic acetate, but rather as acetylic phenylate.—(*Zeitschr. Chem.*, N.F., iii. 196.)

Phenol, Sulphoacids of (C=12).—A. Kekulé. The author considers the so-called phenylsulphuric acid to be a sulphoacid, containing a residue of sulphuric acid in a similar manner as nitro compounds contain a residue of nitric acid. He gives it the formula

$$C_6H_4\left\{\begin{array}{l}OH\\ \left.\begin{array}{r}S''O_2\\ H\end{array}\right\}O\end{array}\right.$$

in place of the old one,

$$\left.\begin{array}{r}C_6H_5\\ S''O_2\end{array}\right\}O$$
$$H\Big\}O.$$

The action of sulphuric acid on phenol, however, gives rise to the formation of two isomeric bodies—phenolparasulphuric acid and phenolmetasulphuric acid The salts of the first being less soluble in water than those of the latter, their separation is easily accomplished by fractional crystallisation. If the phenolsulphuric acids still contain their original hydroxyl, as is assumed here, the hydrogen of the latter will be replaceable by an alcohol radical, without thereby causing a change in the general character of the sulphoacid. If methyl be introduced, sulphoacids will be formed, identical in composition with the acid obtained from anisol with sulphuric acid.

This substitution is effected by heating phenolpara- (or meta-) sulphuric acid with potassic hydrate, alcohol, and the iodide of the desired alcohol radical in sealed tubes.

The potassic salts of the phenolmeta- and phenolparasulphuric acid thus obtained resemble each other so closely that it is difficult to say to which of them the corresponding anisol compound belongs; but it is believed that there also exist two isomeric anisolsulphuric acids. The author also is of opinion that the action of sulphuric acid on aromatic compounds nearly always gives rise to substitution compounds.—(*Zeitschr. Chem.*, N.F., iii. 197.)

Monochlorphenyl (C=12).—Ed. Dubois has succeeded in obtaining monochlorphenol by passing a slow current of chlorine through cooled phenol. 500 grms. of phenol were taken, and the action of chlorine continued for twelve hours. On distillation, the portion going over between 212° and 225° C. was collected separately and rectified. He finds the compound thus prepared identical with the monochlorphenol obtained by the action of sulphurylchloride on phenol. Nitric acid converts it into dinitromonochlorphenol. Griess has obtained this body by treating phenol first with chlorine, and then, without previous purification of the chloro-compound, with nitric acid. The author believes he has observed differences between his compound and that of Griess, and it would, therefore, appear probable that in the latter chemist's case first di- or trichlorphenol was formed (vide *Ann. Chem. Pharm.* cxx. 286), which afterwards exchanged a portion of the chlorine against nitryl.—(*Zeitschr. Chem.*, N.F., iii. 205.)

Aluminic Sulphates, Basic(O=8).—H. Debray. Zinc in contact with platinum (or lead) is readily acted upon by a hot solution of alum. A precipitate is formed of the composition of Lowigit;

$$KOSO_3+3(Al_2O_3,SO_3)+9HO,$$

which is almost insoluble in strong chlorhydric or nitric acid, but attacked by sulphuric acid. Heated to low redness it loses nearly all its water; at a still higher temperature it decomposes into alumina and potassic sulphate. Finally powdered calcic carbonate digested in the cold with a solution of alum in excess forms a salt, readily soluble in dilute acids. Its composition is

$$4Al_2O_3,3SO_3+36HO\ .$$

A solution of aluminic sulphate in excess, boiled with zinc or platinum, forms a precipitate soluble in dilute acids; dried at 100°C., its composition is $SAl_2O_3,3SO_3+20HO$.—(*Bull. Soc. Chem.* 7, 9.)

Nitrotoluol.—A Kekulé, in a previous communication (*vide* Chemical News, No. 386), confirmed Jaworsky's statement, that the crystalline nitrotoluol is the pure compound, and the liquid not an isomeric modification of it, but simply a mixture of the pure with some other bodies. He now publishes some experiments he made with both the solid and the liquid nitrotoluol. If ordinary nitrotoluol is distilled, the greater portion goes over between 220° and 225° C.; the fraction distilling above 233° soon solidifies. The latter is purified by repeated distillation and crystallisation from alcohol or ether. The nitrotoluol thus prepared boils at 237° C., and crystallises readily. Nirtic and sulphuric acid convert it into dinitrotoluol. On oxidation with potassic bichromate and sulphuric acid, paranitrobenzoic acid (nitrodracylic acid) is formed; the oxidation proceeds more readily than it does with ordinary nitrotoluol, and a better result is attained, both as regards quantity and quality. Toluol prepared from toluolsulphuric acid yields by careful treatment a nitro compound which after the first distillation solidifies to a great extent. From the facts—1st, that on liquid nitrotoluol being reduced with tin and chlorhydric acid, no hydrocarbon is observed to be given off with the vapours of water: 2ndly, that the toluidine prepared from liquid nitrotoluol contains aniline; and 3rdly, that a mixture of pure nitrotoluol and nitrobenzol on distillation behaves in a very similar manner to ordinary nitrotoluol—the author believes that the liquid state of ordinary nitrotoluol is due solely to an admixture of nitrobenzol. As to the source of this benzol in those cases where it was not originally present in the toluol, the author thinks it possible that under favourable conditions nitric acid acting on toluol (methylbenzol) might destroy the methyl, and, substituting nitryl, form nitrobenzol.—(*Zeitschr. Chem.*, N. F., iii. 225.)

Hydrocarbons, Solid, from Coal-tar. Fritzsche (C=6).—The hydrocarbon $C_{28}H_{10}$, investigated by Anderson, and considered by that chemist to be the anthracene of Dumas and Laurent, the author believes to have been a mixture of the pure $C_{28}H_{10}$ with other hydrocarbons of lower melting points. The melting point given by Anderson is 180° C., by Dumas and Laurent 213° C., by Fritzsche (five years ago) 210° C.

The author has now succeeded in obtaining this body in a state of perfect purity, and, though unable as yet to give an exhaustive comparison of its properties with those of the accompanying hydrocarbons of coal-tar, he has established some characteristic reactions, which will suffice for their identification.

The body $C_{28}H_{10}$ separates from its solutions usually in thin, flat crystals, which are never twisted and always of a definite shape. The best mode of observing this is to dissolve a small quantity in a drop of ether on a glass plate; on evaporation a spot is left which appears transparent, but under the microscope is seen to consist of a mass of crystals which, especially along the edge, are well-formed hexagonal plates. The transparency and crystalline structure of the spot are peculiar to this body, which, by that means, can be distinguished from another closely related to it. This latter body dissolves more readily in ether, and leaves a spot less transparent, showing a crumpled appearance at the edges. The spot produced by a mixture of the two is white, perfectly opaque, and with the rim as before.

On cooling an alcoholic solution of the body $C_{28}H_{10}$, flat leaf-shaped crystals, either hexagonal or rhombic, appear, which grow on the sides of the vessel. The other body, under these conditions, forms a voluminous mass of thin twisted plates, which remain suspended in the liquid. A mixture of the two always shows the latter mode of crystallisation. It is then, however, easily seen, with a magnifying glass, that the crystals are not homogeneous.

The method employed by the author for the separation and purification of the body $C_{28}H_{10}$ consists in dissolving the raw material in coal-tar naphtha, redissolving again the first portions that are separated from the solution, and repeating this process several times, until the above-described characteristic phenomenon of crystallisation is observed. To free the body from a yellowish colour, caused by an admixture of chrysogene, its hot solution in coal-tar naphtha is exposed to direct sunlight. On cooling the bleached liquid, large crystals of the pure material are obtained. It is well to treat them finally with a boiling alcoholic solution of picric acid, which removes any admixture of a body of much higher melting-point.

The melting-point of the pure body $C_{28}H_{10}$ the author has never found higher than 207° C.

The behaviour of this body towards light is very remarkable. If a cold saturated solution of it is exposed to direct sunlight, microscopic crystals soon appear, varying in shape according to the nature of the solvent—elongated hexagonal plates from coal-tar naphtha, four-sided rhombic ones from alcohol. These crystals differ greatly from the mother substance. They are almost insoluble in any solvent, and are altogether very indifferent; but if they are melted (a higher temperature being required than for $C_{28}H_{10}$) they are converted again into the original body $C_{28}H_{10}$.

The action of nitric acid on $C_{28}H_{10}$ gives rise to a number of other compounds. The mode of operating was as follows: —The powdered substance was mixed with glacial acetic acid, and nitric acid added drop by drop. The liquid assumes a yellow colour, and, if heat be avoided, a clear dark yellow solution is obtained. On addition of water a resinous precipitate is formed; if the liquid is allowed to stand, evolution of gas gradually sets in, and crystalline bodies are precipitated. If it is heated to 50°—60° C., red vapours are given off, and crystals separate. Of these various derivatives the author describes three:—

1. A colourless body, soluble in alcohol and benzol, which separates from the latter in monoclinometric crystals; is decomposed by continued boiling with acetic acid; forms a precipitate, which combines with picric acid, on adding a basic substance to its alcoholic solution.

2. Large, colourless, prismatic crystals. An alkali added to their solution in alcohol colours the liquid dark orange, and an acid is formed, the potassic salt of which crystallises in red needles. A current of ammonia passed through its benzolic solution produces a dark red amorphous precipitate.

3. A body endowed with the property of combining with nearly all solid hydrocarbons from coal-tar as well as with retene and idrialine. The body is obtained in microscopic crystals, sparingly soluble in most solvents, but soluble to some extent in benzol.

This new nitro-body combines with $C_{28}H_{10}$, forming beautiful large violet crystals of the rhombic system. If they are heated to 170°—180°C., the body $C_{28}H_{10}$ is volatilised, and the nitro-compound remains behind. They also decompose on being dissolved in benzol, the nitro-compound crystallising first; or if treated with acetic or nitric acid, in which case the hydrocarbon is extracted.

Besides the body $C_{28}H_{10}$, the author has obtained from coal-tar three others (α, β, γ) melting at about 190° C., one (δ) melting at about 235° C., and another (ϵ) at about 100° C. Neither of them, however, has been obtained pure. They all combine with the new nitro-compound, which combination furnishes the chief means of distinguishing them from each other.

α, the body already alluded to as resembling closely $C_{28}H_{10}$, gives with the nitro-compound a dark red-brown substance, much less soluble than that produced by $C_{28}H_{10}$. Like the latter, it is converted, on exposure to light, into a "para-" compound.

β forms with the nitro-compound a dark green product.

γ, an orange-coloured, insoluble compound, crystallising from benzol in needles. This body is insoluble even in hot concentrated sulphuric acid.—(*Bull. Acad. Imp. Petersb.* vii.)

Toluol- and Benzol-sulphurous Acid—R. Otto (C=12, O=16). Toluolsulphurous acid, heated with water to 150° C. in sealed tubes, splits up into toluolsulphuric acid and a body of the composition C_7O_8SO, according to the following equation:—

$$2C_7H_8SO_2 = C_7H_8SO_3 + C_7H_8SO.$$

The new body is not acid, is insoluble in water, readily soluble in hot alcohol, from which it separates in rhombic crystals. Zinc and sulphuric acid convert it into metabenzylsulphhydrate.

The decomposition of benzolsulphurous acid takes place in a similar manner.—(*Zeitschr. Chem.*, N. F. iii. 262.)

Acids with Water at High Temperatures.—W. Markownikoff and Th. v. Purgold (C=12, O=16). Citric acid, when heated with water in sealed tubes to 160° C. splits up into carbonic anhydride and itaconic acid, according to the following equation:—

$$C_3H_4(HO)\left\{\begin{array}{l}CO.OH\\CO.OH\\CO.OH\end{array}\right. = C_3H_4\left\{\begin{array}{l}CO.OH\\CO.OH\end{array}\right. + CO_2 + H_2O.$$

Similar reactions are obtained with tartaric, quinic, lactic, anisic acid, and some substitution-compounds of benzoic acid.—(*Zeitschr. Chem.*, N. F., iii. 264)

MISCELLANEOUS.

Chemical Society.—The next meeting of the Society will be held on Thurday evening, at 8 o'clock, when a lecture "*On the Mode of Representation afforded by the Chemical Calculus, as contrasted with the Atomic Theory*," will be delivered by Sir B. C. Brodie, Bart. A large attendance of Fellows and visitors being anticipated on this occasion, the Royal Society have kindly placed their large meeting room at the disposal of the Chemical Society for that evening.

Dr. Odling's Lecture on the Absorption of Gases by Metals.—Our verbatim report of the above lecture was not returned corrected by the author in time for insertion in this number, but will certainly appear in our next.

The Paris Exhibition.—One of our earliest contributors, who is at the same time an eminent scientific chemist and a valued member of our editorial staff, is on the point of starting for Paris. His attention will be more especially directed to the English department of the Chemical Exhibition, and the results of his observations will be placed before our readers in a series of articles. These will be in addition to the usual articles forwarded weekly by our Exhibition correspondent.

British Association of Gas Managers.—The fourth annual general meeting of the members of this Association is announced to be held at Nottingham on the 11th, 12th, and 13th of June, when the following papers will be submitted:—"*The Utilisation of the Residual Products of the Manufacture of Coal Gas, with especial reference to the Production of Aniline Colours from Coal Tar*," by Dr. Letheby, M.B., M.A., etc., Professor of Chemistry in the College of the London Hospital, Gas Analyst and Medical Officer of Health for the City of London. "*On the Practical Working of the Liquor System of Purification;*" being a statement of results in continuation of the paper of last year on "An Improved Method of Purifying Coal Gas," by Mr. George T. Livesey, South Metropolitan Gasworks, London. "*On the Purification of Gas from Ammonia, and the Utilisation of the Product*," by Mr. George Anderson, London. "*Notes on the Manufacture of Sulphate of Ammonia*," by Mr. W. Esson, Gasworks, Cheltenham. "*On the Application of Liquid Hydrocarbons as a Substitute for Cannel in the Manufacture of Gas of High Illuminating Power*," by Mr. E. Goddard, Gasworks, Ipswich. "*Some Remarks on the Explosive Properties of Fire-damp and Coal Gas, with Particulars of Experiments made in Lighting Portions of the Oaks Colliery with Pit Gas*," by Mr. J. Hutchinson, Gasworks, Barnsley. "*On Leakage from Gas Mains*," by Mr. E. S. Cathels, Gasworks, Crystal Palace District. "*On the Valves of Gas Purifiers*," by Mr. W. J. Warner, Gasworks, South Shields.

Action of Charcoal in Removing Organic Matter from Water.—Mr. Edward Byrne has examined how far the statements generally made with regard to the action of charcoal in purifying water might be depended on. Nearly five pounds of new and freshly burned animal charcoal, of the degree of fineness used in sugar refineries, were packed in an ordinary stoneware filter. The water employed contained, in the gallon, organic matter, 10·80 grains; inorganic matter, 88·30 grains. The hardness before boiling, was found to be 50·50°, and after, 33°; and the oxygen required to oxidise the organic matter contained in one gallon amounted to 0·0116 grain. Several gallons of the water were allowed to percolate slowly through this charcoal, and, upon examination afterwards it was found that, of the *inorganic matter*, 52·60 grains were removed from the first gallon, but from each succeeding gallon less and less, so that, from the twelfth gallon that passed through the charcoal, only 8·80 grains of inorganic matter were removed. Of the *organic matter*, 4·80 grains were removed from the first gallon; but, with a gradual decrease, the charcoal ceased to remove any after the sixth gallon. In fact, immediately afterwards, it commenced to give back a portion of the organic matter removed in the first instance, the quantity returned to the twelfth gallon amounting to 1·55 grain. Thus, of the 13·54 grains of organic matter removed by the charcoal from the first six gallons of water, as much as 4·98 grains were given back to the next six gallons, from which the author concluded that, had this set of experiments been carried a little further, all the organic matter removed at first by the charcoal would have been given back again. The author, in conclusion, gave it as his opinion that, by chemical agency, bad water could be purified to a very limited extent only. [Mr. Byrne has overlooked the important fact that the efficacy of charcoal as a filtering agent for the removal of organic matter does not depend upon mechanical absorption, but upon oxidation; and from his drawing no distinction between the removal, by charcoal, of the inorganic and the organic impurities of the water, it would seem as if he were ignorant of this property. A few ounces of charcoal, used properly, will oxidise a pound or more of organic matter. Charcoal has not fair play in a filter unless it is occasionally allowed an opportunity of absorbing atmospheric oxygen.—Ed. C. N.]

Composition and Quality of the Metropolitan Waters in May, 1867.—The following are the returns of the Metropolitan Association of Medical Officers of Health:—

Names of Water Companies.	Total solid matter per gallon.	Loss by ignition.*	Oxidisable organic matter.†	Hardness.

Death of Pelouze.—We have to announce the death of one of the best and most celebrated French chemists, M. Pelouze, Master of the Mint in Paris, which took place on the 31st ult. The previous day he had been attacked by heart dropsy, and he expressed an urgent desire once more to breathe the pure air of the heights of Bellevue (near Meudon). No sooner was he in the carriage than a faintness came over him from which he recovered with much difficulty. His family yielded to his wish by taking him to the desired spot, where he arrived in the evening only to die on the following morning at 7. Since the sudden death of his excellent and distinguished wife he pined away, notwithstanding the affectionate attentions paid him by his son and three daughters. He was born at Valonges in the department of the Manche, in 1807, and was, at his first outset of life, a simple laboratory student. He became successively Professor at the Polytechnic School, Professor at the French College, Member of the Academy of Sciences, Verifier of the Mint Assays, Member of the Municipal Council of Paris, Director of the St. Gobain Glass Works, and, lastly, President of the Commission of the Mint, the highest post that a practical chemist can aspire to. M. Pelouze died with resignation, and in the faith of a Christian. He was buried at Montmartre Cemetery, in the family tomb, the corpse being followed by an immense *cortège*, composed of all the *élite* of society, the principal members of the Academy, six carriages of the Municipal Council, and the National Guard in full uniform. M. Fremy, the distinguished chemist of the *Conservatoire des Arts et Métiers*, delivered the usual funeral oration.

Action of Light on Chloroform.—The chloroform used for the experiments had a specific gravity of 1·492 at 70° F., was absolutely free from acid reaction, and imparted no coloration whatever to sulphuric acid. The diluted chloroform was made of eight ounces of the former, by the addition of one fluidrachm of strong alcohol. The bottles used for the occasion were made of flint glass, of uniform size and shape, and filled alike. The experiments lasted one week during the hot days in August. It was concluded from these experiments:—1. That in order to preserve pure chloroform of specific gravity 1·49, it should be kept totally excluded from the light. 2. That to keep chloroform in the daylight, it should be reduced in specific gravity by the addition of about two fluidrachms of 95 per cent. alcohol to one avordupois pound of chloroform, sp. gr. 1·492. During the repetition of some of these experiments, attention was drawn to the presence of moisture in some of the bottles, and it was determined to try its effects on chloroform; accordingly, chloroform of 1·492, dried by standing over chloride of calcium, was kept in absolutely dry bottles, and in bottles slightly moist, and both kinds exposed to diffused daylight and direct sunlight. The bottle containing the moisture always showed the presence of free chlorine much sooner than the dry one, though the entire absence of moisture would not be sufficient to preserve the chloroform unaltered. But, if the chloroform had been reduced in specific gravity to 1·475 or less, the presence of several drops of water in the bottle would not induce the liberation of chlorine after an exposure of two weeks to the direct sunlight. For medicinal purposes—that is, for inhalation—this amount of alcohol would be unobjectionable, since it amounts in one fluidounce only to about forty drops.—*J. M. Maisch, Proc. Am. Pharm. Assoc.*

Chemical Society.—The next meeting of the Society will be held on Thursday evening, at 8 o'clock, when the following papers will be read:—"*On Derivatives of Hydride of Salicyl,*" by Mr. Perkin; "*Analysis of Biliary Concretion,*" by Dr. Phipson; "*On Pyrophosphoric Acid,*" by Dr. Gladstone.

Magnesium.—We understand that the Magnesium Metal Company are progressing in the manufacture of magnesium wire and riband. They have found from experience that if magnesium riband is pressed broader and thinner, and by this means made to present a larger surface to the oxygen of the atmosphere for the same weight of metal, it burns much more steadily and surely. They are now supplying the metal in this form.

Extractum Conii.—Dr. John Harley has proved by experiment that the ext. conii is a very uncertain, if not an inert, preparation. He attributes this to the fact that the active principle of the plant is, to a certain extent, vaporisable, even at a natural temperature of 70° to 90° Fahr., and that a prolonged exposure to a high temperature is accompanied by a progressive diminution of the conia, the alkaloid being converted into ammonia and some other secondary product. It is, therefore, necessary, in order to obtain an extract

---

* The loss by ignition represents a variety of volatile matters, as well as organic matter, as ammoniacal salts, moisture, and the volatile constituents of nitrates and nitrites.

† The oxidisable organic matter is determined by a standard solution of permanganate of potash, the available oxygen of which is to the organic matter as 1 is to 8; and the results are controlled by the examination of the colour of the water when seen through a glass tube two feet in length and two inches in diameter.

Hy. Letheby, M.B.

of full power, to expose the juice in shallow dishes to a rapid current of dry air having the temperature of 150° Fahr. By this process, an extract containing one per cent. of conia may be procured.—*Pharm. Journal.*

Sublimation of the Alkaloids.—Dr. Guy suggests the following mode of procedure:—Provide small crucible covers or slabs, or fragments of white porcelain, a few microscopic cell-glasses, with a thickness of about one-eighth of an inch and a diameter of circle of about two-thirds of an inch, and discs of window-glass about the size of a shilling. Place the porcelain slab on the ring of a retort-holder, then the glass cell, and upon the porcelain, in the centre of the cell, a minute portion of the alkaloid or other white powder or crystal reduced to powder. Then pass the clean glass disc through the flame of the spirit lamp till the moisture is driven off, and adjust it over the glass ring. Now apply the flame to the porcelain, underneath the powder, and continue to heat till the powder undergoes its characteristic change and gives off vapour. Watch the deposit of this vapour on the glass disc, and remove the spirit lamp, either directly or after a short interval, as experience may determine. By this process Dr. Guy has succeeded in getting very beautiful crystalline sublimates of morphia, strychnine, solanine, and cryptopia. He recommends it in preference to that of Dr. Helwig.—*Pharm. Journal.*

Cryptopia.—Messrs. T. and H. Smith have discovered a new alkaloid in opium, which they have named cryptopia. It is extracted from the weak spirituous washing of crude precipitated morphia, but the quantity yielded by opium is very small, Messrs. Smith having operated upon four or five tons of opium, and only obtained five ounces of muriate of cryptopia. They have prepared the sulphate, muriate, nitrate, thebolactate, and the acetate; these all crystallise in beautiful and distinct forms, but the alkaloid itself has much better defined crystalline forms than any of its compounds. Its primary form is a hexagonal prism, and it is obtained in this condition if crystallised slowly in a tube from its alcoholic solution. The formula of the new alkaloid is $C_{23}H_{25}NO_5$.—*Pharm. Journal.*

Preparation of Hydrate of Sodium from Sodium.—At the recent *soirée* of the Pharmaceutical Society, a large block of pure fused hydrate of sodium, prepared from metallic sodium, was exhibited, and excited much attention. It is thought that a short account of the means adopted to oxidise so explosive a substance may not be without interest to our readers. Sodium, as prepared for the market, is cast in moulds, which are well smeared with oil, which coats the metal and prevents it oxidising; but the sodium from which the hydrate is made is cast in bright clean moulds. When removed it is well rubbed with a clean linen cloth, in which it is encased to prevent contamination from the atmosphere. The bars of sodium are now cut into lumps about one inch square. One of these lumps is thrown into a perfectly clean silver dish, which floats on a stream of cold water. A few drops of distilled water are poured on the sodium, and the vessel is well agitated by hand, which prevents explosions. When the first lump of sodium is dissolved, another piece is thrown in, additional drops of water are added, and the vessel kept constantly agitated, and so on throughout the operation. After a deposit of soda forms at the bottom and around the sides of the vessel, and the liquid becomes completely saturated, the tendency to explosions seems much reduced. If the dish remains quiet, great amount of heat is generated, and the fusing sodium bursts out like a tiny volcano, scattering globules of fire—*i. e*, burning sodium—all around; but if the vessel is kept in constant motion, a fresh surface of cold water is brought into contact with the fusing sodium, its temperature is reduced, and explosions are almost prevented. The milky liquid thus prepared is now filtered, and then fused in a silver crucible, over a gas furnace to a dull red heat, or until all moisture is driven off and the liquid becomes perfectly transparent. The crucible is carefully covered up, and the contents allowed to cool; but as the hydrate of sodium is very deliquescent, absorbing moisture even when too hot to be handled with impunity; it is removed from the crucible whilst warm, quickly broken into lumps, and placed in well-stoppered bottles. The operation is, at the best, a slow and tedious one, accompanied with an unpleasant smell and some annoyance, as, with the utmost care, explosions cannot be entirely avoided. A steady workman will dissolve up, working with one dish, about 1½ lb. of sodium per day, but he could be trained to take charge of two dishes.

Preparation of Dilute Phosphoric Acid.—Introduce into a French glass tubulated retort, of capacity of forty-two parts, twelve parts of water and two parts of phosphorus. Place the retort on a sand bath, and introduce through a funnel tube, fixed in the tubulure by means of a cork and reaching half an inch below the level of the liquid, eight parts of nitric acid. Apply gentle heat, and watch the operation closely as soon as reaction commences. When the reaction slackens add more nitric acid in portions of about one-fourth part at a time. Should the reaction become violent, small quantities of warm water must be added until it is reduced to its ordinary action, which may be compared to the gentle boiling of water. The formation of frothy bubbles on the surface of the liquid is always the forerunner of violent reaction, and should be checked at once. I have found that if it was checked at this stage, a comparatively small amount of water would answer, but if allowed to react violently a much larger quantity of water was necessary. The evaporation of the acid, after the phosphorus is all oxidised, is conducted in a porcelain capsule; towards the end of this process it will froth up, owing to the rapid disengagement of nitric oxide. The dish must therefore have about three times the capacity of the acid when concentrated, and a little distilled water should be kept conveniently near, to add in case there is danger of frothing over. It is scarcely necessary to add that the operation should be conducted under a good furnace hood, or otherwise the beak of the retort should be introduced into a good flue.—*C. L. Diehl, Am. Pharm. Assoc.*

Determination of Arsenic in Sulphide of Arsenic.—To determine the arsenic contained in sulphide of arsenic—an operation often necessary for the estimation of arsenic—M. Graebe uses a standard solution of iodine, as in the estimation of arsenious acid. Suspend the sulphide of arsenic in water, add some carbonate of soda, then a little starch paste, and the standard solution of iodine. (It is evidently necessary that the sulphide of arsenic should be freed from sulphuretted hydrogen.) The reaction takes place according to the equation—

$$AsS_3 + 5I + 5HO = AsO_5 + 5HI + 3S.$$

—*Journal für praktische Chemie*, xcvi. 261.

Volumetric Estimation of Lead and Tin.—M. Graeger determines the lead by ferrocyanide of potassium; the decomposition takes place according to the equation—

$$2(PbO,NO_5) + 2(KCy),FeCy = 2(PbCy),FeCy + 2KO,NO_5.$$

Ferrocyanide of lead is almost insoluble in acids, and its precipitation is easy. The author employs a standard solution of ferrocyanide of potassium; when all the lead is precipitated, the liquid colours ferric salts blue, which may be tested in one drop of it. An excess of ferrocyanide may be added, and determined in the filtered liquid by permanganate of potash. As a control, the ferrocyanide of lead may be suspended in water, and titrated by permanganate. Tin, in the state of bichloride, may be estimated in the same way, but not when in the state of protochloride; in that case it must be first changed to bichloride.—*Journal für praktische Chemie*, xcvi. 330.

Larkin's Magnesium Powder Lamp.—It is a singular circumstance that England, so pre-eminently the home of mechanical invention and skill, should hitherto have failed to produce a good lamp for the combustion of magnesium. A lamp answering this designation must be simple in construction and certain in its operation, the light must be continuous and well under control, and mechanical skill should help to economise a light necessarily costly from the present limited scale of its production. Mechanical ingenuity ought also to assist the continuance of a flame liable to go out so long as it relies for its source upon one solitary wire or ribbon. The best magnesium lamps hitherto invented have come from America, which country has far distanced England in the applications of magnesium, and in the ingenious construction of apparatus for consuming it. In making these remarks we intend no disparagement to Solomon's lamp. It was constructed with the object of assisting photographers, on dull, wet, and foggy days, to follow their avocation. And as it was early found that from four to eight grains of magnesium were sufficient to take a single portrait, a lamp working from three to five minutes was amply sufficient, and this want Solomon's lamp supplied; but for those manifold uses where the light was required for a longer period, one or other of the American lamps had to be used. But this slur upon English mechanical ingenuity no longer exists. In Larkin's magnesium powder lamp we have a lamp adapted to many requirements. It is very simple in construction, and it need not be a very costly lamp. In it the light is continuous and absolutely under control; the combustion of the metal, and the light arising therefrom, is also greatly economised. The leading features of the lamp are these:—A reservoir, funnel-shaped, and attached to it a long narrow tube, at the end of which is placed a small spirit lamp—these, with mechanical details controlling and guiding each part, constitute the whole of the invention. And yet it will be easily seen that these principles are capable of a great variety of modifications of form and of manifold application. For instance, in the reservoir can be placed, according to the brightness of the flame required, either pure magnesium reduced to dust, or magnesium powder, mixed one-half, two-thirds, or three-fourths with sand, or, if a coloured flame be required, nitrate of strontia or other chemical substances can be added. These mixtures flow down the funnel-shaped tube—as sand flows down the common hourglass—and through a small spirit flame placed at the orifice of the tube, where the magnesium ignites into a continuous flame; the spirit flame insures the ignition of the magnesium, and prevents the fouling and blocking up of the tube by the oxide of magnesium, which would otherwise form around the exit tube. The mixture can be stopped or turned on, as required, by means of a small finger tap. In this way the combustion of the metal is economised, and the amount of light and its continuity are absolutely under control. The hand-lamp now before us, constructed on this principle, is light and portable, hardly exceeding in size an ordinary watchman's lantern. It is not easy to predict the uses opening out for so bright a light and so portable a lamp, but they must be very numerous. It seems admirably adapted for valuing mines and surveying underground workings. It might be used with great advantage in deep sea fishing, and as a decoy light by sportsmen and naturalists; it may also before long be used for lighthouse purposes, and for lighting the entrance to harbours and signalling at sea.

On the Decomposing Action of High Temperatures upon some Sulphates,[*] by M. Boussingault.—It appears from the experiments made that the sulphates of lime, magnesia, lead, etc., are decomposable at a white heat, and that, in consequence, in analytical researches, their calcination should be made only at a moderately elevated temperature; and, although the complete separation of the elements of the acid of the sulphates of strontia and baryta does not take place except at the melting heat of iron, precaution must be taken in their calcining, as it appears certain that the decomposition of these sulphates commences at a much lower temperature. As to the volatilisation of the alkaline sulphates, this must be taken into careful consideration when vegetable ashes are being examined and their proportions estimated; for, if the ashes are obtained at a high temperature, a perceptible loss of alkaline salts takes place, especially those of potassium, which are more volatile than those of sodium.

General Metallurgical Method of Messrs. Whelpley and Storer.—For the application of the chemical portion of this process, the ore must be in the state of very fine powder. The calcination of the ore in this state takes place in what is called a water-furnace. This consists of a fire tower about 20 feet high, 3 feet in diameter at the top, and 4 feet at the base, built of brick with double walls, and having a large water tank at the bottom. Around the upper portion are four fire boxes, opening into the tower, which is closed and connected with a large fan-blower. By this means, besides the supply of air heated by passing between the two walls of the tower, air and fuel, in the state of dust, are carried down into the furnace. The heating effects obtained are very surprising. In the calcination of sulphuretted ores, only a moderate temperature and a large supply of oxygen are required. The fire tower of the water furnace being heated to redness, the ore, with or without pulverised fuel, is driven by a small fan down the tower. The sulphur and base metals are rapidly oxidised, and the calcined ore falls into the water-tank below, the current of air being carried through successive chambers open to the tank beneath. In the case of sulphuretted ores of copper, the water-tank is filled with a solution of the chlorides of sodium and calcium, by which, with the aid of a spray wheel at the end where the air current has exit, the sulphurous acid is absorbed, and the oxide of copper converted into the dichloride. Mr. T. Sterry Hunt, F.R.S., finds the reaction to take place according to the following equation:—

$$\mathrm{CaCl + SO_2 + Cu_2O_2 = CaSO_4 + Cu_2Cl.}$$

The dichloride of copper is held in solution by the chloride of sodium. A small portion of protochloride of iron generally occurs in the solution, which is separated by addition of oxide of copper, according to this equation:—

$$\mathrm{Cu_3O_3 + Fe_2Cl_2 = Cu_2Cl + CuCl + Fe_2O_3.}$$

The addition of milk of lime precipitates the whole of the copper as hydrated oxide; simultaneously the bath is regenerated.

The British Association of Gas Managers held a very successful congress at Nottingham on the 11th, 12th, and 13th inst., under the presidency of Mr. Hawksley. About eighty members attended, and thirty-eight new members were elected, the total number now amounting to 178. Several interesting papers were read, including the continuation by Mr. G. T. Livesey of his communication "*On the Practical Working of the Liquor System of Purification;*" a paper by Mr. G. Anderson "*On the Extraction of Ammonia from Gas, and the Utilisation of the Product;*" a communication "*On the Application of Liquid Hydrocarbons as a Substitute for Cannel,*" by Mr. E. Goddard. Mr. E. S. Cathels read a paper "*On Leakage from Gas-mains;*" and papers "*On the Manufacture of Sulphate of Ammonia,*" by Mr. W. Esson; "*On the Explosive Properties of Firedamp,*" by Mr. J. Hutchinson; and "*On the Valves of Purifiers,*" by Mr. W. J. Warner, were also read. Dr. Letheby, as on former occasions, delivered a lecture to the Association, the title of it being "*The Utilisation of the Residual Products of the Manufacture of Coal Gas, with especial Reference to the Production of Aniline Colours from Coal Tar.*" The learned author is preparing a full report of this lecture for our columns. It was agreed to hold the congress in London next year, when a large accession to the number of members is expected to take place, as the metropolitan gas managers, who have hitherto kept aloof, will most probably take that opportunity of joining the Association.

---

[*] Read before the Academy of Sciences, June 10.

NOTES AND QUERIES.

Manufacture of Sulphuric Acid.—Sir,—I see by the Chemical News of April 26 (just received), that you propose to aid manufacturers by placing them in communication with competent parties to get them out of their difficulties. Now, I am in connexion with a company who have been for some time past manufacturing sulphuric acid from sulphur, but now wish to use pyrites, and desire to know the best process for that purpose. Our chamber is of the ordinary construction, and of the capacity 29,000 cubic feet. We have already built four pyrites kilns; the internal capacity of each is about 1·51 m., and the distance these are placed from the chambers is 21 m., connected by an acid-proof earthenware tube of 0·50 m. diameter. Is this distance and tube sufficient to arrest any foreign matter the mineral may contain from getting into the chamber, and do you consider the kilns of good shape for burning Huelva or St. Domingo's ore freely? My object is to be placed in communication direct with a practical person who would give me all the information for working a chamber with pyrites on the best known plan, by correspondence and plans, if possible; and, if not, I would go or send a person to England for that purpose. Of course a fair remuneration would be given for the information. We concentrate our acid to 66 deg. Baumé in a platinum still. Would pyrites acid distil perfectly colourless, and as pure as that made from sulphur?—T. G. H., Lisbon.

Chinese Blue.—Sir,—In answer to the inquiry for the way to make Chinese Blue, I beg to say that I am quite able to show it for a consideration. I have been a colour-maker twenty years.—Samuel Johnson.

Estimation of Tartrates.—Sir,—In the Chemical News, No. 390, May 24, 1867, it is stated that a manufacturer of tartaric acid has expressed his willingness to give 100*l.* to any one who should succeed in discovering a correct and ready method for the estimation of tartaric acid in tartrates. Would you kindly give me the name of the manufacturer?—Chemicus.

[The statement is made on the authority of the authors of the book reviewed. Perhaps Mr. Watts will kindly give the required reference.—Ed. Chemical News.]

Palm Oil.—Reply to "Milo," May 24:—The quantity of chrome necessary to bleach 1 cwt. of palm oil varies with the kind of oil, of which there are several in the market. It may vary from 0·85 to 1·25 lb. Care should be taken to purify the oil from all foreign matter; else more chrome will be required.—"Bleach."

Chinese Blue.—Sir,—A substance called "Chinese Blue" has been referred to several times recently amongst your "Notes and Queries." I should feel much obliged to any of your correspondents who would tell me what is the composition of this substance.—"Learner," St. Helen's, Lancashire.

Naphthaline.—Sir,—Is there any process (heat excepted) by which naphthaline can be kept liquid?—W. B.

Carbon Biscuits.—Sir,—Can any of your readers kindly supply me with a recipe for making "carbon biscuits;" also where they are to be procured?—Sheff.

Dyeing Fancy Leather.—Sir,—I should be glad if you could inform me where I can purchase a work on dyeing and dressing fancy leathers, &c., and similar articles.—E. Church.

Repairing Looking-glass.—Sir,—I have a large looking-glass, with a patch of silvering about as large as a shilling rubbed off in the centre. Can I mend it? I am acquainted with the mode of making looking-glasses, and should think that with plenty of mercury and a piece of tinfoil somewhat larger than the bare spot, there would be no difficulty. Before I begin, I should, however, like to know what the experience of others may have been.—J. Thompson.

Santonine.—Sir,—In answer to your correspondent, I can recommend chloroform as a solvent for santonine for preparing good microscopic slides. Dissolve santonine in six or eight times its weight of chloroform, and allow a drop to fall on a glass slide and evaporate spontaneously. Beautiful rosettes of crystals will be left. They can be mounted with Canada balsam, or may be viewed dry.—F. R. W.

Sodium.—Sir,—If any one can give me a hint as to the best means of preserving sodium, I shall be greatly obliged.—N. Tyne.

Packing for Pumps for Corrosive Liquids.—Sir,—If one of your numerous correspondents would tell me what sort of packing I could use for a chemical pump, he would confer a great boon upon me. I want it for a plunger pump, to lift chloride of lime liquid. Yarn is eaten away in a few days. Vulcanised india-rubber is not affected by the "bleach," but there is a difficulty in screwing it tight.—M. James.

Carbon Biscuits.—Sir,—I cannot tell your correspondent "Sheff." how to make carbon biscuits, but I can strongly recommend highly carbonised bread as equally efficacious. Doubtless this mixed with flour and water would make good charcoal biscuits.

Dyeing Fancy Leather.—Sir,—If your correspondent, E. Church, will refer to O'Neill's "Chemistry of Calico Printing," or to the Dictionary of Calico Printing and Dyeing, by the same author, he will find a great deal of very useful information on this subject. Hunt's edition of Ure's Dictionary of Arts, article "Leather," also contains much that he will find useful.

Chinese Blue.—"Learner," St. Helen's, Lancashire, wishes to know the composition of Chinese blue. It is one of the synonyms of "Prussian blue," which is also called indifferently Paris, Berlin, and mineral blue. Full practical account in Watts's Dict., art. "Pruss. Blue," also under head "Ferricyanides," p. 245, subheading "Potassio-Ferrous Ferricyanide."

Repairing Looking-glass.—Sir,—J. Thompson will find that the plan he speaks of will repair the bare place; but there will generally be a mark at the outer circumference of the pool of mercury. I strongly advise him to scrape all the amalgam off, and deposit a coating of pure silver on the glass. By following Browning's excellent directions (quoted in your last volume) he will be able to do this in a few hours.—A. Milo.

Zinc Paper.—Sir.—Could you afford me information about buying or making zinc paper, covered on one side, as tin paper is?—J. C. J.

Packing for Pumps for Corrosive Liquids.—Sir,—Has Mr. James tried packing the piston with cork fibre? He will find this answer perfectly, and not be acted on by the chlorine.—F. W., Runcorn.

Production of Heat by Percussion.—Sir,—In many elementary works on science it is stated, as an illustration of the above, that blacksmiths are in the habit of hammering a cold nail on the anvil until it becomes red hot. Have any of your readers ever known of this being done? Can the heat rise to such intensity? Would not the cooling influence of the anvil be sufficient to keep the heat from rising to redness? and would not the iron be flattened out to foil first?—Scepti.

Preserving Sodium.—Sir,—The simplest and at the same time the most effective means of preserving sodium, is to immerse it completely in oil—Young's paraffin oil is the best—and then to place it in an empty air-tight jar or bottle. It ought to be immersed in oil after every time of using.—M.

Destroying Ants.—Sir,—My house is infected with a very small kind of ant, which at some seasons so swarm about the kitchen cupboards as to be a nuisance. Can you tell me how to get rid of them? They are much smaller and paler in color than the common garden ant.—E. M.

Use of Superheated Steam.—Sir,—I wish to try a plan of turning superheated steam through an ordinary evaporating pan. Now, I wish to know if any of your readers are aware if this plan has been tried, and with what result? Instead of passing the steam through the pipes of the pan direct from the steam-boiler, I propose to pass the steam through a superheater, and then through the pipes of an evaporating pan, such as may be used for boiling ale, alum liquor, etc. Information on this point will oblige.—S.

Gilding and Silvering.—Sir,—Can any of your correspondents inform me how to obtain dead or matt gilding, similar to what is seen on French clocks? Also, by whom are watch-dials gilt and silvered?—W. Smith.

Ants.—Sir.—I got rid of the ants in my house by adopting the suggestion you yourself made—viz., putting carbolic acid into the holes whence they were seen to issue. A few doses were effectual.—J. Th.

Wood Engraving.—Sir,—A Leipzig wood-engraver, particularly skilled in natural history illustrations, wishes to find a scope for his abilities among British publishers of illustrated scientific works. Perhaps some readers can tell whether there is a want of skilful artists of his kind felt in this country, or whether there is not much chance for a foreigner in this department.—G. L.

Preservation of Sodium.—Sir,—Permit me to observe the following:—Sodium is best of all kept and preserved by coating it with a layer of pure paraffin. I find that the well-known Professor Rud. Wagner, of Würzburg, recommended this mode of preserving sodium some time since, and that it is applied with perfect success. Of course some precautions are necessary, and first and foremost amongst these are, that only *pure* paraffin should be used; that, by being kept in a fused state previously to being applied for this purpose, it should be freed from water entirely; and then that it should be fused at its lowest melting point, 50 deg. Cels., and the sodium (melting point 95 deg.—96 deg. Cels.) immersed in it at no higher temperature than (say) from 55° to 60°. It is easy to remove the coating of paraffin when the sodium is wanted for use.—A.

ANSWERS TO CORRESPONDENTS.

⁂ All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E. C. *Private* letters for the Editor must be so marked.

⁂ In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Articles by D. Forbes, F.R.S., T. Sherlock, and Dr. Phipson are in type, but are unavoidably postponed. Our report of last Monday's meeting of the Academy of Sciences arrived too late for insertion in this number.

F. S. J.—Evidently chalk and paraffin oil.

Studiosus.—You will be safe in following Dr. Mohr's directions. Dr. Hassall has written a work "On Urine," which will give you much information. You can also consult with advantage Lehmann's "Physiological Chemistry," Golding Bird's treatise "On Urinary Deposits," and Beale's treatise "On Urine, Urinary Deposits, and Calculi."

F. S. J.—To determine the sulphur in argillaceous iron ore, dissolve a weighed quantity of ore in nitro-hydrochloric acid, evaporate, etc., to separate the silica; dissolve the residue in acid; dilute, and precipitate the sulphuric acid with chloride of barium. The weight of sulphate of baryta obtained, multiplied by 0·13734, gives the sulphur.

X. Y. Z.—If you apply to our publisher, he will send the numbers you require, if they are in print. Occasional copies of our first and second volumes are to be met with; but they are worth far more than their publishing price.

A Miner.—It is not at all proved that our coal supply will run short for the next three or four hundred years, and in the meantime there will certainly be many discoveries made by which, if coal cannot be superseded altogether, its waste may be diminished. This is the most important problem; for nine-tenths of the coal raised is absolutely wasted, so far as the utilisation of the available force it is capable of exerting is concerned. Dr. Frankland, speaking of coal gas, says that physical science has yet scarcely attempted to estimate the true light-giving power of any sample of gas; but it can be proved, from the laws of conservation of force, that the light obtained by an argand burner is certainly less than the 1-265th of the light which could possibly be obtained from the same gas consumed at the same rate. Our problem now should be to try and get some of this enormously greater amount of light out of our gas. But we need not be dependent upon coal for gas. An ingenious Frenchman has lately propounded a brilliant idea. His theory (advanced through the medium of *La Gazette Médicale de Lyon*) is that all dead bodies of human beings are at present wasted, when they might as well be utilised by distillation into gas, to be used for illuminating purposes. He remarks:—"Coal is being exhausted, and since the human carcase is capable of supplying a gas of good illuminating power, why should it not be employed to this end? In India the idea is already realized. By a process of combustion in retorts a corpse of common dimensions may be made to yield twenty-five cubic metres of illuminating gas, which, at a cost of twenty-five centimes per cubic metre, would give a value of about eight francs for a body of ordinary size."

Communications have been received from C. Greville Williams; W. M. Bywater; H. Cross; J. W. Swindells; G. F. Bodwell; Sir B. C. Brodie, Bart.; S. Wilson; W. Odling; Rev. F. Souley Johnstone; S. Mordan; W. Briggs; C. H. Heaton; Dr. Adriani; T. A. Readwin; A. H. Church; T. Twining; Dr. W. S. Squire; A. C.; S. Meller; Runcorn Soap and Alkali Company; R. E. Bibbey; S. Muspratt, M.D.; Hadland and Co., with enclosure; E. Parnell; T. L. Phipson, Ph. D.; Cearnen; W. Lang; E. Stock; Joseph Thorley; Wm. L. Carpenter; Samuel Johnson; E. Church; Dr. Lish; G. Foord; P. Jessop; Dr. Price (with enclosure); W. Valentin; C. R. C. Tichborne; S. T. Tillman; Professor Joy; J. W. Swindells; G. Burditch; Johnson and Matthey; H. R. Marsden; Dr. W. T. Robertson; J. Bedford; R. H. Wilkinson; G. F. Rodwell; E. C. C. Stanford; Dr. W. Allen Miller; E. Church; Rev. J. L. Gordon; L. Mond; W. White; E. P. H. Vaughan; S. Hunt; S. Muspratt; H. L. Rayner; H. K. Bamber, F.C.S.; Geological Society; H. Sugg; C. R. Wright; R. Oxland; Mr. McDonnell; James Blackhouse; Gossage and Sons; A. E. Hawkes (with enclosure); W. Smith; Dr. H. Letheby; Charles Cochrane (with parcel); Henry Deane (with enclosure); John Wilkinson (with enclosure); J. Atkinson; Chas. U. Wright (with enclosure); Alex. Parkes (with enclosure); Dr. Odling; Rev. E. Smith; Dr. Odling; Johnson and Matthey (with enclosure); the Assistant-General Secretary to the British Association; Dr. Gladstone; F. Field; F. O. Ward; S. Mellor; Dr. R. Angus Smith (with enclosure); W. Schofield; J. Levincke; H. Walker; Dr. Letheby; H. Hofman; S. Baker; A. Watt; W. Millward; J.C. Todd; H. Henderson; E. Rothwell; Dr. A. Miller; John Bray, F.C.S.; Geological Society; H. H. Watson (with enclosure); Dr. Apjohn (with enclosure); Ritchie and Co.; Savory and Moore; Sir Henry James; Mr. Worthen; McDougall and Co.; Henry Hall; Sir B. C. Brodie, Bart.; John Pollard; August Stromeyer; Dr. Rohrig (with enclosure); Sir B. C. Brodie, Bart.; T. Sterry Hunt; E. Fairland, M.D.; Dr. S. Muspratt; S. Mellor; J. Jenkins; E. P. H. Vaughan; Dr. Lunge; C. Greville Williams, F.R.S.; J. Lawrence Smith (Vice-President of Jury, Group 4, Paris, 1867); Dr. Wm. Allen Miller, F.R.S.; the Board of Trade: Burnard, Lack, and Co. (with enclosure); May and Baker; J. S. Parker; J. Swain Window; John Parry; W. Browning; Samuel Collins.

Books Received.—"Gas Manipulation," by U. T. Sugg; "An Index to Mineralogy: being an Alphabetical List of about 2500 Minerals, with concise References to their Composition, Synonyms, and Place in the British Museum," by T. Allison Readwin, F.G.S.; "A Guide to the Chemical Department of the Museum of the Royal Agricultural College, Cirencester. Part I.—The Mineral Collection," by A. H. Church, M.A.; "Science made Easy," by Thomas Twining, Esq.; "New Theories of the Universe," by James Bedford, Ph. D.; "The Technologist," June; Transactions of the American Institute for 1865-6; "Photographs of Eminent Medical men," by W. T. Robertson, M.D., etc.; "Natural Philosophy," by C. Brooke, M.A., F.R.S., etc.; "The Mixture-book;" "Germinal Matter and the Contact Theory," by James Morris, M.D. Lond.; "Journal of Materia Medica," No. 5; "Chemical Physics," by Dr. Wm. Allen Miller, F.R.S; "Arithmetic Simplified for General Use," by Neil Arnott, M D., etc.

Ferrum.—Add a little caustic soda to the water, and you will find that the iron axles and shaft will not rust so readily.

Jehu.—Apply to Professor Tuson, at the Veterinary College, Camden Town. We cannot answer such questions.

S. K. Rawfolds.—Miller's "Chemistry," Bloxam's "Chemistry," Watts's "Dictionary of Chemistry," Fresenius' "Qualitative and Quantitative Analysis," and Sutton's "Volumetric Analysis," will form a good foundation for the chemical library of your Mechanics' Institute.

J. T. Gordon.—The name and address of the inventor of the ice-making machine are given in the article describing the machine. See page 29 of this volume, No. 372.

Fire-damp Indicator.—A few weeks ago the *Scientific American* advised a correspondent, who had applied for Mr. Ansell's address, to forward the letter to the "care of W. Crookes, England." Our American contemporary will be glad to know that the advice was taken, and was perfectly successful. The letter has been forwarded to Mr. Ansell.

Glycerin Soap.—We have received from the manager of Price's Patent Candle Company samples of a new preparation of toilet soap. It contains half its weight of pure distilled glycerin, and is apparently free from cocoanut oil or excess of alkali. The glycerin is solidified by dissolving in it an equal weight of fine toilet soap. This article, from its containing so large a proportion of glycerin, if exposed to the air, attracts moisture and becomes sticky. It has been found to lather and wear well, and has a fragrant perfume. The value of glycerin as a remedy for chapped or irritated skins is now well known.

Iron Eggs.—A correspondent draws our attention to the following statement in an American paper, and asks if any one can throw light upon the subject:—"Eggs with iron shells will be a fact at the Paris Exposition. A Berlin chemist caused his hens to produce them by feeding them on a preparation in which iron was made to take the place of lime." We should be sorry to throw doubts on the authenticity of the statement, but we pity the poor chickens! Probably, however, they were *canards*, not hens, which were experimented on. Would the iron eggs be thick enough to be used against armour plating? Boiled hard, they would serve as solid shot, and, if sucked and filled with powder, they would make capital shells, as effective against our iron-clads as any other foreign-made shells would probably be.

Errata.—Dr. Miller has called our attention to two misprints in our report of his first lecture. Page 260, twenty-two lines from bottom, *for* "magnesium," *read* "magnesia;" page 262, seventeen lines from bottom, *for* "light," *read* "eye."

Q.—Spelter is the commercial name for zinc.

F. Stephens.—Artificial ivory, for billiard-balls, has been made from a mixture of paper pulp, sulphate of baryta, and gelatine. They are said to be quite equal to ivory balls.

C. L.—Apply to Mr. Sutton, Eastern Counties Laboratory, Norwich. He will supply you with all the requisites for volumetric analysis.

Dr. Adriani wishes us to state that his last letter was forwarded, together with a former letter on the same subject, and was intended as a private communication. That being the case, Dr. Adriani should have given some intimation that his letter was not intended for publication.

A. B. C.—1. Amongst aqueous solutions having powerful affinity for oxygen, you may find the following useful:—A solution of pyrogallic acid in potash; an ammoniacal solution of subchloride of copper; a mixture of potash and solution of ferrous sulphate. You may, perhaps, find it useful to absorb oxygen by shaking together copper turnings and very dilute sulphuric acid. 2. The mixture explodes rather violently, and has more than once occasioned serious injury. 3. In taking photographs of the spectrum, we did not find that the point of maximum intensity of deposit was in the slightest degree influenced by the base of the bromide, iodide, etc., used in conjunction with the silver salt.

E. Fairland.—Speaking generally, it is correct to say that the heat from the sun will pass through glass, whilst the rays from a dark source of heat are intercepted. The reason for this is that glass is opaque to heat-rays of the refrangibility of those proceeding from a dark source of heat, whilst it is transparent to those coming from a body so hot as to be brightly luminous.

Physicus.—It is recorded that galena is slightly volatile in the vapour of water, at a high temperature. This might, therefore, account for what you have observed.

J. Bynner.—A gallon of water is required to be converted into steam to drive a railway train a little more than 100 feet. Each puff of steam ejects about half a pint.

F. Carte.—Phosphoric acid solution will take the enamel off a glazed iron dish, but it will not attack good Berlin porcelain.

Still another New Material for Gas Making.—*Apropos* to the suggestion we published recently for turning bodies into gas, a correspondent tells us that, according to a Swiss journal, a means has been discovered of utilising cockchafers. The *Estafette* of Lausanne states that between four and five millions of those insects were recently sent to Friburg for the manufacture of gas, and the residue was found to form an excellent carriage-grease.

J. G. T.—We think that the new iron and sulphuric acid pile of M. Monthier differs in some respect from Callan's battery, although it might be considered a "colourable imitation" of it.

Carbo.—Pure caramel may be obtained by placing a solution of crude caramel on a dialyser. The undecomposed sugar and some other matters pass through into the water, whilst the caramel remains behind. It forms when dry a black, highly lustrous mass, soluble in water when it has been evaporated without heat, but insoluble when it has been dried over a water bath.

W. S.—The process of depositing silver on glass, which we quoted in full in the review of Browning's "Plea for Reflectors," is the best for your purpose.

R. H. M.—You will find Dr. Roscoe's "Treatise on Chemistry" give you full information.

C. H.—The Act compels the condensation of 95 per cent. of muriatic acid gas, but in most works the condensation is more than 99·5 per cent. The average for this year has been 99·27 per cent.

May.—Cyanide of potassium will remove stains caused by nitrate of silver. Remember that it is very poisonous.

Physicus.—If matter be not infinitely divisible, it is, at all events, sufficiently so for all purposes of experiment, or even reasoning. Schiaparelli concludes that the *matter* in a sphere of meteoric cloud 100 miles in diameter weighs about 15 grains; if that be not infinite divisibility, it is a very near approach to it.

THE CHEMICAL NEWS.

ON THE APPLICATION OF THE BLOWPIPE TO THE QUANTITATIVE DETERMINATION, OR ASSAY OF CERTAIN METALS.

BY DAVID FORBES, F.R.S., ETC.

(Continued from Vol. XV., p. 282.)

Silver Assay. Cupellation Loss.—This term is applied to indicate a minute loss of silver, unavoidably sustained in the process of cupellation, which arises from a small portion of that metal being mechanically carried along with the litharge into the body of the cupel. The amount of this loss increases with the quantity of lead present in the assay (whether contained originally in the assay or added subsequently for the purpose of slagging off the copper, etc.); it is relatively greater, as the silver globule is larger, but represents a larger percentage of the silver actually contained in the assay, in proportion as the silver globule obtained diminishes in size. It has, however, been experimentally proved that in assays of like richness in silver, this loss remains constant when the same temperature has been employed, and similar weights of lead been oxidised in the operation.

In the blowpipe assay this loss is not confined to the ultimate operation of cupellation, but occurs, though in a less degree, in the concentration of the silver-lead, and in the previous scorification of the assay, had such operation preceded the concentration. The total loss in the blowpipe assay is found, however, to be less than in the ordinary muffle assay, since in the latter case the whole of the oxidised lead is directly absorbed by the cupel.

In mercantile assays of ore it is not customary to pay attention to the cupellation loss, and the results are usually stated in the weight of silver actually obtained. Where, however, great accuracy is required, especially when the substances are very rich in silver, the cupellation loss is added to the weight of the silver globule obtained, in order to arrive at the true percentage.

The amount to be added for this purpose is shown in the annexed table, which is slightly modified from Plattner's.

The use of the table is best explained by an example, as the following:—An assay to which there had been added, in all, five times its weight of assay lead, gave a globule of silver equivalent to six per cent. Upon referring to the table, it will be seen that the cupellation loss for this would be 0·07; consequently the true percentage of silver contained in the assay would be 6·07. This table is only extended to whole numbers, but fractional parts can easily be calculated from the same.

When the globules of silver are so minute that they cannot be weighed, but must be measured upon the scale, the cupellation loss should not be added, since, as a rule, it would be less than the difference which might arise from errors of observation likely to occur when measuring their diameters upon the scale.

In the case of beginners, it will be found that the cupellation is usually carried on at too high a temperature, and that thereby a greater loss is occasioned than would be accounted for by the annexed table. After some trials the necessary experience will be acquired in keeping up the proper temperature at which this operation should be effected.

Actual percentage of silver found by assay.	Cupellation loss, or per-centage of Silver to be added to the actual per-centage found by assay in order to show the true per-centage of silver contained in the same. The entire amount of lead in or added to the assay being the following multiples of the original weight of assay:—

Silver Assay.

It now becomes necessary to consider in detail the processes requisite for extracting the silver contents (in combination with lead) from the various silver ores, and other argentiferous compounds, which are met with in nature or produced in the arts.

In considering these, the following classification of the substances will be found convenient:—

I. METALLIC ALLOYS.

A. Capable of direct cupellation.

- *a.* Consisting chiefly of lead or bismuth: silver lead and argentiferous bismuth, native bismuthic silver.
- *b.* Consisting chiefly of silver: native silver, bar silver, test silver, precipitated silver, retorted silver amalgam, standard silver, alloys of silver with gold and copper.
- *c.* Consisting chiefly of copper: native copper, copper ingot, sheet or wire, cement copper, copper coins, copper-nickel alloys.

B. Incapable of direct cupellation.

- *a.* Containing much copper or nickel, with more or less sulphur, arsenic, zinc, etc.; unrefined or black copper, brass, German silver.
- *b.* Containing tin; argentiferous tin, bronze, bell metal, gun metal, bronze coinage.
- *c.* Containing antimony, tellurium, or zinc.
- *d.* Containing mercury: amalgams.
- *e.* Containing much iron: argentiferous steel, bears from smelting furnaces.

II. MINERALISED COMPOUNDS.

- *a.* Silver and other ores, furnace products, sweeps, and products of the arts containing sulphides, arsenides, and other compounds of the metals in combination with more or less earthy matter.
- *b.* Argentiferous sulphide of molybdenum.

c. Substances nearly free from sulphides or arsenides, but containing chlorine, iodine, or bromine.

d. Argentiferous litharge, and other easily reducible oxides.

I. A. Metallic Alloys capable of direct Cupellation.

a. Consisting chiefly of Lead or Bismuth.—In determining the silver contained in these alloys, it is only requisite to place a clean piece of the same, weighing about from one to ten grains according to its probable richness in silver, upon a cupel of coarse bone ash, and proceed by concentration and cupellation exactly as has been already described under these heads.

Should the substance be not altogether metallic, or not free from adherent slag, earthy matter, or other extraneous matter, it should previously be fused on charcoal with a little borax in the reducing blowpipe flame, and the clean metallic globule then removed from the charcoal, and treated as before. In order to remove the globule from the inherent borax-glass, it may be allowed to cool, and then detached; or, after a little practice, it will be found easy, by a quick movement of the charcoal, to cause the globule still melted to detach itself completely, and drop on the anvil in the form of a single somewhat flattened globule, without suffering any loss of lead adhering to the charcoal.

In the case of argentiferous bismuth alloys the process is carried on in all respects the same as if silver-lead were being treated. As, however, the bismuth globule is very brittle, care must be taken when separating the concentrated globule from the litharge, as, if not carefully done, a loss may easily be sustained from a portion of the globule remaining behind adherent to the litharge. It is better, therefore, to remove the litharge by degrees from the globule with the aid of the forceps.

Argentiferous bismuth, free from lead, when cupelled alone, invariably leaves a globule of silver, having a dull frosted surface. If, however, at the end of the operation a small quantity of lead (¼ to ⅓ a grain) be added, and fused along with it, the silver globule then obtained will be perfectly bright and free from all bismuth.

In the case of native bismuthic silver it is advisable to fuse the previously weighed mineral with a little lead and borax-glass on charcoal in the reducing flame, so as to free it from any adherent earthy matter, and then proceed by concentration and cupellation, as before described.

Silver Assay.

I. A. Metallic Alloys capable of direct Cupellation.

b. Consisting chiefly of silver: native silver, bar, test, and precipitated silver, retorted silver amalgam, standard silver, silver coin, and other alloys of silver with gold and copper.

These alloys may be at once fused with lead on the cupel itself, and the operation finished as before described. In general, however, it is better to fuse the weighed assay previously with the requisite amount of pure lead and a little borax-glass, say from a quarter to half the weight of assay, in the reducing flame at a low heat on charcoal until the globule commences to rotate. This ensures having a perfectly clean button of silver-lead, which is then cupelled in the ordinary manner.

In most cases the quantity of lead to be added need not exceed that of the weight of the alloy, but when several percentages of copper are present in the assay, as in case of many coins, etc., the lead should be increased to some three, or even five times the weight of the assay in proportion to the amount of copper actually contained in the substance under examination, and which will be treated of more at length under the head of copper-silver alloys.

When no more lead has been added to the assay than its own weight, the cupellation may be concluded in one operation by inclining the stand, and so moving the globule on to a clean part of the cupel; but when more copper is present, it is preferable to concentrate first and cupel subsequently, in order thereby to reduce the cupellation loss to its minimum.

In the concentration as much copper as possible should be slagged off with the lead, which is effected by inclining the cupel somewhat more than usual, so that its surface may be less covered up with the litharge and exposed as much as possible to oxidation, by which means the litharge, as it forms, is enabled to carry off more of the copper contained in the silver lead.

Should the silver globule after cupellation show indications of still containing copper, as before noticed, when treating of cupellation, a small quantity of lead must be fused along with it, and the cupellation finished as usual.

As at the present time no means are known by which silver can be separated from gold by the use of the blowpipe, in all cases of alloys containing gold, this metal remains to the last along with the silver, and the result in such cases always indicates the combined weight of both these metals contained in the alloy under examination. The employment of the humid assay must be resorted to for effecting their separation:—

c. Containing chiefly copper: native copper, ingot, wire, or sheet copper, cement copper, copper coins, copper-nickel alloys.

Under the most favourable conditions in cupellation, the amount of lead requisite when converted into litharge to slag off one part of copper along with it as oxide, amounts to between seventeen and eighteen parts its weight. In the blowpipe assay it is usual to add to any cupriferous alloy an amount of pure lead equal to twenty times the amount of copper contained in the alloy, in order to ensure the whole of the copper being separated in the litharge. In the case of nickel the amount of lead required is somewhat less than with copper, but in practice the same amount of lead may be employed.

When the copper is quite clean the requisite amount of lead may be added to it in a single piece on the cupel, fused and cupelled as usual, after previous concentration of the silver-lead to a small-sized globule.

It is generally found, however, that traces of iron, slag, gangue, or other foreign matter is present; and, consequently, it is usually advisable to fuse the assay along with the requisite amount of lead, and about one-half its own weight of borax-glass in the reducing flame, until the whole of the substance is seen to have perfectly combined or alloyed with the lead, and the globule has come into brisk rotation, whilst at the same time no detached metallic globules are seen in the borax-glass.

The concentration of the silver-lead and cupellation are then conducted as usual, taking care when concentrating to incline the cupel-stand so as to expose as much of the metallic surface of the melted globule to the oxidising action of the air as possible, with a view of enabling the litharge whilst forming to carry off as much copper along with it as possible.

Should the silver globule obtained after cupellation spread out, or appear to the eye more flattened than usual with globules of pure silver, it indicates that some copper still remains, and a small piece of assay lead (½ to 1 grain weight) should be placed alongside it whilst still on the cupel, fused together, and the cupellation finished on a clean part of the same cupel as usual.

Precipitated or cement copper, especially that which is in the crude state, and has not been melted and run into ingots, is often very impure, containing so much iron, lead, arsenic, earthy matter, etc., as not to admit of direct cupellation, and in such case should be treated as pertaining to class B. *a.*:—

B. Metallic Alloys incapable of direct Cupellation.

a Containing much copper or nickel, with frequently some little sulphur, arsenic, zinc, iron, cobalt, etc., as unrefined or black copper, brass, German silver, etc.

As the presence of these extraneous matters would interfere with the cupellation either by causing a loss of silver-lead projected from the cupel upon the evolution of the volatile substances present, or by forming oxides which could not be absorbed by the cupel, it is necessary to eliminate such substances by a scorification with borax on charcoal previous to concentration or cupellation.

In the case of unrefined and black copper, the portion used in the examination is placed in the scoop with twenty times its weight of assay lead, and its own weight of powdered borax-glass, mixed with the spatula, and transferred to a soda-paper cornette. It is then fused on charcoal in the reducing flame, which should be constant and uninterrupted, until all particles have completely united, and a brisk rotation sets in, which is kept up for a short time, when the silver-lead globule, which should appear bright on the surface after cooling, is concentrated and cupelled precisely as is directed under A. *c*. By this preliminary scorification the sulphur, arsenic, and zinc are volatilised, and any lead, cobalt, or iron slagged off into the borax-glass.

In the assay of brass and German silver the quantity employed is fluxed with its own weight of borax-glass, but only requires ten times its weight of assay lead. The operation is commenced as before, but the globule is kept somewhat longer in rotation (always keeping the flame directed only on to the borax-glass), so as to allow the zinc present to be completely volatilised, which is evident when the surface of the silver-lead becomes bright, on which the heat is increased for a few moments to expel the last traces of that metal, and the silver lead thus obtained is concentrated and cupelled as before.

The silver globule obtained from the cupellation of substances rich in copper generally requires the addition of a small quantity of lead and re-cupellation (as before described), in order to ensure its freedom from copper.

Behaviour of Lime when Burned.—Dorlhar and Saminn. Two cylinders rormed out of the same piece of limestone measured 27 millimètres in length and 17 millimètres in diameter. After being completely burned their volume had increased nearly 1-10th—viz., to 28 millim. and 17·7 millim.—*Berg. und huttimm, Zeitung*, 1867.

NOTE ON THE CALCULUS OF CHEMICAL OPERATIONS.

BY PROFESSOR WILLIAMSON, F.R.S.

The remarkable memoir of Sir Benjamin Brodie, respecting which these remarks are made, is the first consistent attempt to introduce analytical reasoning into the body of the science of chemistry.

One fundamentally important question of method is raised by the memoir; and as it may be considered apart from the rest of the subject, and is, in fact, a preliminary to any discussion upon it, the author wishes to draw attention to some considerations relating to it.

Sir B. Brodie defines a chemical operation as an operation performed upon the unit of space, of which the result is a weight. The unit of matter (or molecule) adopted is the weight of matter of a specified kind, which occupies in the state of perfect gas the volume of one litre at 0°C. and a pressure of 760 millimetres of mercury.

This absolute definition is intended to supersede the prevailing theory that the molecule of each compound is the smallest proportional weight in which we can, consistently with its other properties, represent it as taking part in any reaction, or in which we can suppose it to exist by itself.

In some cases the vapour-densities of many compounds have confirmed the molecular weights assigned to them by a comparison of their reactions; but in other cases, many of which are too familiar to need mention here, the vapour-density contradicts the above evidence of the molecular weight. What is the result in such a case of conflict? Uniformly this: that if the vapour-density and reactions are irreconcileable, we know that the vapour-density must have given wrong advice, and it only remains to be seen by an examination of the anomalous vapour how the molecule broke up on evaporation.

Perhaps the best way to judge of the working of the new definition is to see the manner in which Sir B. Brodie himself applies his principle. Thus, at page 817 of his memoir, the units of thirteen substances are given, and opposite each formula is given the "absolute weight in grammes" of a litre of the vapour, and in another column the "relative weights" of each. Of these fundamental statements four only—viz.: the numbers for sulphur, sulphuretted hydrogen, sulphurous acid, SO_2, and sulphuric acid, SO_3, are the records of observations. The numbers for three other substances are at variance with observation, for SO_3H_2 breaks up on evaporation into SO_2 and H_2O, forming a mixed vapour of about half the density given. SO_4H_2 breaks up similarly, forming a vapour of about half the specific gravity assumed, and Nordhausen acid first breaks up into SO_3 and SO_4H_2, and this hydrate decomposes at a higher temperature, as above mentioned. The vapour from Nordhausen acid has, therefore, a specific gravity vastly below that assumed. No doubt there are good reasons derived from a study of other facts for believing that these three compounds, *if they were capable of evaporating undecomposed*, would have the vapour densities assigned to them by Sir B. Brodie; but taking the simple definition as given, we are led to molecular weights, which the author, in common with all chemists, considers inadmissible, and which he very properly corrects.

The other six substances of the table are more unstable compounds, which have never been evaporated without even more permanent and fundamental changes in their composition. It would be easy to multiply instances, but enough has been said to illustrate the fact that molecular formulæ are not deduced from mere vapour densities, and that we should only be justified in taking a fixed vapour volume, as the definition of molecules, if we could show that from the vapour densities of compounds their molecular weights could be inferred with certainty.

There are strong reasons against the supposition that the molecules of chemistry can all, or nearly all, exist in the state of vapour. If we were to speculate upon the probable distribution of the elements at a temperature sufficiently high for the volatilisation of all known substances, it would be safe to assume that a very great if not the greatest, number of known molecules would be resolved into others containing a smaller number of atoms.

Numberless known molecules are notoriously broken up at temperatures within easy reach of every operator, and there is reason to anticipate that the progress of research will gradually give us more insight into the conditions of condensation which distinguish volatile from non-volatile molecules, so as to explain why the latter cannot exist in the gaseous state.

It is, moreover, not only undesirable on the ground of accuracy, but also exceedingly inconvenient, to define chemical molecules as being one litre of vapour, for the artifice necessitates the establishment of a new scale of atomic weights and molecular weights.

The molecule of hydrogen in this scale weighs				0·089
"	"	"	oxygen	1·430
"	"	"	nitrogen	1·251
"	"	"	chlorine	3·173
"	"	"	steam	0·805
"	"	"	ammonia	0·760
"	"	"	hydrochloric acid	1·631

The numbers represent in grammes the weight of a litre of the respective substances.

If we retain the ordinary molecular weight—viz.:

Hydrogen	2	=	H_2
Oxygen	32	=	O_2
Nitrogen	28	=	N_2
Steam	18	=	H_2O
Ammonia	17	=	NH_3
Hydrochloric acid	73	=	ClH

we have numbers which are easily remembered and easily used, and which answer all the purposes of the other numbers, in a far more convenient manner. Relations between these short numbers are seen at a glance, and computations are rapidly made with them in the head, which, with the numbers of the *crith* series of the litre, are comparatively slow and difficult. Calculations relating to any absolute measure are most easily made upon the basis of the common molecular weight. One constant has to be used for the reduction in absolute volume—viz.: 11·2 litres, or the volume, at the normal temperature and pressure, of one gramme of hydrogen. Every formula of a volatile molecule represents 22·4 litres of the vapour weighing as many grammes as there are units in the molecular weight.

Some interesting considerations are suggested by the proposal to consider the molecule of hydrogen as containing only one atom, and the molecules of chlorine, bromine, iodine, nitrogen, phosphorus, arsenic, etc., as each compounded of one atom of hydrogen with two atoms of elements at present unknown. The formula for hydrochloric acid is $\alpha\chi$, which we may define, $\alpha\chi = \mathrm{HCl}$, and this combined with the fundamental assumption $\alpha = \mathrm{H}_2$, gives us

$\mathrm{H}_2\chi = \mathrm{HCl}$, whence $\chi = \frac{\mathrm{Cl}}{\mathrm{H}}$. In like manner the symbol of chlorine, $\alpha\chi_2$, may be translated into ordinary symbols by the aid of the equation $\alpha\chi_2 = \mathrm{Cl}_2$, in which we replace α and χ by their values as above.

$$\mathrm{Cl}_2 = \mathrm{H}_2.\frac{\mathrm{Cl}_2}{\mathrm{H}_2}$$

In explanation of the symbol $\frac{\mathrm{Cl}}{\mathrm{H}}$ it is merely stated that it represents an atom of chlorine from which an atom of hydrogen is removed. Chemists employ the sign of multiplication to denote combination, as in HCl, and the sign of division is here employed to indicate decomposition.

The assumption that two molecules of hydrochloric acid decompose so as to form a single atom of hydrogen necessarily involves for a molecule of the acid a formula like $\alpha\chi$, representing it as one atom of hydrogen to which another atom $\frac{\mathrm{Cl}}{\mathrm{H}} = 34{\cdot}5$ is united.

$\mathrm{H}_2\frac{\mathrm{Cl}}{\mathrm{H}}$ is the translation of the formula of hydrochloric acid; and when two such molecules are decomposed into hydrogen and chlorine, the process consists in removing H_2 from one of them, and combining the residue $\frac{\mathrm{Cl}}{\mathrm{H}}$ with the other molecule of acid, forming $\mathrm{H}_2\frac{\mathrm{Cl}_2}{\mathrm{H}_2}$

In like manner hydrobromic acid is described by the symbol $\mathrm{H}_2.\frac{\mathrm{Br}}{\mathrm{H}}$.

Bromine ..... $= \mathrm{H}_2.\frac{\mathrm{Br}_2}{\mathrm{H}_2}$

Hydriodic acid $= \mathrm{H}_2.\frac{\mathrm{I}}{\mathrm{H}}$

Iodine........ $= \mathrm{H}_2.\frac{\mathrm{I}_2}{\mathrm{H}_2}$

Ammonia ..... $= \mathrm{H}_4.\frac{\mathrm{N}}{\mathrm{H}}$

Nitrogen...... $= \mathrm{H}_2.\frac{\mathrm{N}_2}{\mathrm{H}_2}$

The author is inclined to think that the hypothesis adopted respecting the constitution of chlorine, nitrogen, etc., might, with advantage, be extended to oxygen and other atoms of even equivalence, if adopted at all, so as to represent those elements as containing hydrogen. Oxygen can be supposed to be built up from water by the addition of an increment of weight, analogous to the increment which transforms hydrochloric acid into chlorine. Water would thus be represented by a symbol of the usual form (say $\alpha_2\phi$), and the decomposition of the unit of water into two units of hydrogen and one unit of oxygen would be represented in a manner analogous to that adopted in the case of hydrochloric acid. One unit of water would lose ϕ, liberating two units of hydrogen, which ϕ would enter into combination with the other unit of water, thereby forming $\alpha_2\phi_2$. $\alpha_2\phi_2$ is thus the symbol of oxygen, and ϕ is an element which is contained in oxygen, and which leaves it to unite with two atoms of hydrogen.

Let α represent	2	grammes of hydrogen	=	22·4	litres.
$\alpha_2\phi_2$ "	32	grammes of oxygen..	=	22·4	"
$\alpha_2\phi$ "	18	grammes of steam ..	=	22·4	"

Then ϕ is the symbol of an imaginary element, representing the increment to be added to 4 grammes of hydrogen, when they are converted into 18 grammes of water. The weight of ϕ is, therefore, 14. It may be translated thus:

$$\phi = \frac{O}{H}, \text{ and if } a = H_2, \text{ we have } 2\ H_2 + H_4\frac{O_2}{H_4} = 2H_4\frac{O}{H_2}.$$

The following equation represents the process:

$$2a + a_2\phi_2 = 2a_2\phi.$$

It is interesting and important to observe that Sir B. Brodie's fundamental hypothesis is an atomic hypothesis, viz., that the molecule of hydrogen consists of one atom instead of containing two atoms, as we have been accustomed to see it; and that, in constructing each molecular formula, he limits himself to some integral number of atomic weights.

In weighing the arguments which will, no doubt, be brought forward in favour of the proposed change, chemists will need to compare the whole of the new system to the old one. Such comparison can only be made when the new systems are before us. The author hopes, before long, to bring forward various considerations relating to the interpretation and application of our present system of chemical facts and theories. He wishes now to point out that the proposed system would be at an unnecessary disadvantage in the comparison or contest, if it were left to rest on the quicksands of conjecture respecting vapour densities.

CHEMICAL COMPOSITION OF STREET MUD.

BY C. R. C. TICHBORNE, F.C.S.

The communication on the above subject, from Dr. Letheby, which appeared in the last number of the CHEMICAL NEWS, possesses to my mind considerable interest from two causes. First—from its important sanitary aspect, and second—from the fact that last year, I endeavoured to bring prominently before the authorities of the city of Dublin, the highly deleterious nature of street dust, or mud, which from their hygienic point of view was vulgarly looked upon as harmless. In a letter published in the *Irish Times*, Tuesday, October 9, 1866, I gave the analysis of the mud taken from one of our narrowest streets, but which street was, and is to the present day, our greatest thoroughfare. The letter was written at the commencement of the severe attack of cholera with which Dublin was visited last autumn, and was published mainly with a view to advocate the use of carbolic acid for watering the roads. On referring to my notes, I find that the street dust in Dublin contained on an average 24 per cent. of organic matter, which is lower than the average given by Dr. Letheby for the London mud, even allowing for difference of moisture. This lower percentage is probably owing to the much larger percentage of animals working upon the same extent of roads, or also because many of our streets are macadamized, or constructed in a similar manner. From the continual state of steeping (if I may use the expression), and re-drying that this comminuted manure is constantly undergoing, I am of opinion that we are hardly alive to the mischief that it is capable of perpetuating. Antiseptics, such as carbolic acid, from their expense, are inadmissible for general use in the ordinary course of events. In seaport towns an efficient antiseptic, and harmless friend, would be found in the sea-water. This should be used freely for watering the streets. In dry and hot weather tbe saline substance very soon accumulates, and the sea-water leaves a perceptible hard crust of the briny matter. From its slightly deliquescent nature it answers its mechanical requirements admirably, and during the usual dry weather adds no expense to the work ordinarily done to restrain the dust. The three and a half per cent. of chloride of sodium, etc., contained in sea-water collects rapidly when exposed to superficial evaporation, even in damp weather, and it would be next to impossible that fermentable changes could take place in the presence of so large a proportion of sea-salts.

Such a project would perhaps be hardly feasible in a city like London, which is situated so far from the mouth of the river, but it could be easily adopted in in such towns as Liverpool, Portsmouth, Dublin, etc. The following analyses taken from my note-book of last year, may possess some interest in connection with my remarks.

Moist Dust from Grafton-street, Dublin, October, 1866.

Moisture	33·3
Organic matter	25·1
Inorganic matter	41·6
	100·0

Street Dust, October, 1866.

Soluble salts	1·3 per cent.
Organic matter	25.1

Soil from a well made road upon which sea-water had been used.

Soluble salts	7.5 per cent.
Organic matter	21·1

Here it will be seen that the salts are about ⅓ the weight af the total organic matters present.

ANALYSIS OF TINKALCITE—$NaO,2BO_3+2(CaO,2BO_3)+18HO$*—DETECTION OF BORON AND FLUORINE IN MINERALS

BY PROFESSOR F. WÖHLER.

After estimating the water of crystallisation, dissolve the mineral in hydrochloric acid, and after neutralising with ammonia, precipitate the lime with oxalate of ammonia. Concentrate the filtrate, and estimate the boracic acid in the state of double fluoride of boron and potassium.

To estimate the soda dissolve another portion of the mineral, precipitate the lime as above with oxalate of ammonia, evaporate the filtrate to dryness, and drive off the ammoniacal salt by heat. Then digest with concentrated hydrofluoric acid, evaporate to dryness, and digest with strong sulphuric acid; all the boracic acid will be carried away in this operation in the form of gaseous fluoride of boron. The sulphate of soda may then be heated to redness in a crucible with a fragment of carbonate of soda.

There are some minerals which contain a rather large quantity of fluorine, silica, alumina and alkalies (principally potash): some also contain soda and lithia, micas for example. Micas being sufficiently heated to disengage fluorine, it must be noticed if they only give off fluoride of silicium, since they contain considerable quantities of silica; the coloration of the blowpipe flame, however, will suffice to indicate the volatilisation

---

* O—8.

of alkaline fluorides. If this occurs, the best plan to adopt is to perform the experiment just described, replacing the lime by silica; all the fluoride of silicium traverses the silica undecomposed, but the alkaline fluorides are arrested and changed into fluoride of silicium, which is evolved, and into silicates of potash, soda, and lithia, which remain in contact with an excess of silica. Take up the silica by distilled hydrofluoric acid; this will change it into fluoride of silicium, whilst alkaline fluorides remain behind. The alkaline fluorides are treated with sulphuric acid, and changed into sulphates of potash, soda, or lithia, and in this mixture the base is to be sought for.

When the object is therefore to determine the fluorine, one can always estimate the water and the fluoride of silicium alone or mixed.

In the case of fluoride of boron the question is not so simple; on heating, some is disengaged from tourmalines, which contain fluorine and boron. The volatile matters contained in a tourmaline may be determined by a process analogous to that employed in the case of fluoride of silicium; the fluoride of boron being changed into a mixture of fluoride of calcium and boracic acid. Unfortunately we do not know a method of estimating boron in mineral substances, especially if associated with fluorine and silicium; so that if we have fluoride of boron, fluoride of silicium, and alkaline fluorides, we can estimate the alkalies, but not the boron, silicium, and fluorine. In the absence of a quantitative method for estimating fluorine, boron, and silicium, we have an excessively delicate qualitative test. The best method of recognising the presence of fluorine consists in mixing the substance with potassic bisulphate, grinding the whole together in a small mortar, and introducing a small quantity of the paste slightly moistened into a glass tube, open at each end; place the substance at the lower part of the tube, and direct a blowpipe flame on to it so as to heat the fluoride.

Under the combined influence of the water in the bisulphate of potash, and that resulting from the combustion of the gas, there are formed alkaline sulphates, with disengagement of hydrofluoric acid. It is true that if there is a sufficient quantity of silica, fluoride of silicium may be formed, but the result will be the same. This gas condenses with the globules of water a little beyond the part heated; if hydrofluoric acid has been formed the glass is attacked, and the same effect is produced if fluoride of silicium has been formed; in the latter case this gas changes in contact with the aqueous vapour into hydrofluosilicic acid and silica; if then the drop of water condensed with the acid is heated, the latter attacks the glass and becomes changed into fluoride of silicium. The glass tube should have been washed and dried carefully, and ought to be transparent; the same precautions must be taken after the operation.

In the case of boron the process is quite different. If no fluorine is present, mix the substance with a small quantity of fluoride of calcium and bisulphate of potash, having previously ascertained that the two reagents do not contain boron; two experiments must therefore be made, one on the reagents, and the other on the substance mixed with the reagents. The mixture is slightly moistened, and held on the extremity of a perfectly clean platinum wire. Direct the reducing flame of the blowpipe on to the paste: at the moment when the mixture appears to boil the flame assumes a vivid green colour, characteristic of boron. When but little boron is present this must not be tried in full daylight, and it should be viewed against a dead black background; the colour of the flame will then be easily detected.

VAPOUR DENSITY OF WATER.

The following remarks, by Mr. F. O. Ward, occur in a private letter recently addressed by that gentleman to a chemical friend. It will be perceived, by the familiarity of the style, and the cursory character of the statements, that this passage was not intended for publication. It contains, however, several indications of interest bearing upon theoretical questions which are at present strongly attracting the attention of chemical philosophers; and we believe that, in submitting it to our readers, we shall not unpardonably overstep the limits of editorial discretion.

"Can you tell me on whose authority rests the assertion that water expands 1,696-fold in becoming steam at 212° F.? It is repeated from book to book, and I have repeated it myself in print (in one of the chapters of Hofmann's "Introduction to Chemistry.") It does not, however, by my reckoning, tally with the vapour-density of water, for

	Gramme.
2 litres of H at 0·0896=..........	0·1792
1 litre of O at 16 × 0·0896=.......	14·3360
	14·5152

The 3 litres being condensed into 2 we have.......................... $\frac{14·5152}{2}=7·2576$

as the vapour density of steam at ordinary pressure and temperature. A litre of water weighs 1000 grammes, and

$\frac{1000}{7·2576}=1377·8$ for the expansion. Reducing the alleged 1,696 for temperature (by $\frac{1}{460}$ per degree F.) from boiling point to 60°=152° we have the ratio

$$\frac{208}{460} \times 1696 = 1266$$ as the expansion

so deduced, against....... .1377·8 as shown above.

Difference.................110·8 (over 8 per cent.)

This is a large discrepancy, and (unless I blunder in my reckoning) it shows error in one or other of the figures compared, which ought not, therefore, *both* to appear (as they do, the 1696 in so many figures, the other *implicitly*,) in the same books (*vide passim* "Fownes' Chemistry," the only one I have with me in my trunk). One question this suggests to my mind is, whether we are not going a little too fast in accepting, as we are all disposed to do, the volumetric relations of bodies as so perfectly symmetrical? Just so, some years back, we were all seduced into the pretty belief that the ponderal relations of bodies were in Prout's simple multiple ratios. Stas stemmed and turned back that false current of chemical philosophy, and we may want a Stas to keep our volumetric opinions in the path of truth!

"The differences as to volume-ratios imputed *en masse* to 'errors of observation,' may, very possibly, have in some cases, an *actual existence*.

"It may well be, indeed, that as, in music, certain minute secondary vibrations give to musical tones their vowel modifications and all the admirable varieties of *timbre* which make up our orchestral wealth; so the small deviations from symmetry in the ponderal and volumetric relations of matter, may be the very conditions of the infinite variety we observe in the modulations of chemical phenomena in those unnumbered surprises of harmony and discord to which we owe the richness and beauty of our chemical orchestra."

F. O. W.

ON A POSSIBLE CAUSE OF VARIATION IN THE WEIGHTS, ATOMIC AND OTHERWISE, OF ELEMENTS AND COMPOUNDS.

BY JOHN A. R. NEWLANDS, F.C.S.

M. Stas has lately remarked that "hitherto nothing has proved that the differences found in certain analyses between experiment and calculation must be *wholly* owing to error in the operation; a certain part may be due to the inexactitude of the law of definite proportions."* It is open for us then to inquire whether any cause exists which should induce the atomic weights of two or more elements to vary in different compounds, or which should make the atomic weight of a compound greater or less than the sum of the atomic weights of its constituents.

If the attraction of gravitation were the sole force concerned in the question, and if the force of gravity be assumed to be always the same for all bodies and at all temperatures, it would seem reasonable enough to believe that the atomic weight of each element would be expressible by an absolutely invariable number, and that the atomic weights of compounds would be absolutely the sum of the atomic weights of their constituents. I of course take it for granted, in this case, that the weighings should be performed in vacuo, and neglect the almost infinitesimal error which might possibly be caused by the amount of the ether of space, displaced by a given weight of matter, being greater in certain forms of combination than in others.

It must not be forgotten, however, that we are living on the surface of an immense magnet, and that all, or almost all, the constituents of the earth's surface are capable of being either attracted or apparently repelled by a magnet with a force which varies with the temperature, the state of combination, etc.; the magnetic attraction of the earth being most powerfully manifested at its two colder points, viz., the two poles.

Among the theoretical consequences of this state of things the following may be mentioned:—1st. A given weight of a magnetic substance would weigh more the lower the temperature, being under the influence of an increasing attraction. Thus, the oxygen of the atmosphere would, during the winter, be drawn to the earth with more force than during the summer; and also, as a general rule, be attracted more in the night than in the day.

2nd. A given quantity of an element would weigh more when in the state in which it was attracted by the magnet than it would in another state. Thus, a given quantity of iron would weigh more in the state of black oxide than in the state of potassium ferrocyanide. The weight of a compound might, therefore, be less than the sum of the weights of its constituents; thus, the weight of ferric oxide, which is but slightly magnetic, would be less than the sum total of the weights of the iron and oxygen it contains, weighed separately, both of these being highly magnetic. By the reverse of this operation, it is possible that the weight of some compounds of certain elements, apparently repelled by the magnet, such as bismuth and thallium, might be greater than the sum of the weights of their constituents.

3rd. The magnetic attraction of the oxygen of the air above any substance might possibly reduce or augment its weight, according as it might be of a magnetic or diamagnetic character.

4th. A portion of the increase of weight which takes place when a given quantity of matter is transferred from the neighbourhood of the earth's equator to that of its poles, may be due to the increased magnetic attraction of the latter. If such be not the case, we should find the gain in weight of iron, under these circumstances, to be no greater than the gain in weight of bismuth.

5th. Admitting the existence of a variety of small bodies, or fragments of planets, meteorites, etc., of all kinds of composition, travelling through space, and approaching from time to time the earth's path in their respective orbits, we should expect to find if they were drawn to the earth by the action of gravity alone, pure and simple, that the substances so falling would be of all shades of composition. On the contrary, if they were drawn to the earth by virtue of its magnetic powers, we should find that the substances so falling would consist entirely, or at least partially, of bodies of a highly magnetic character, such as iron and nickel, and never of diamagnetic substances, such as bismuth and antimony. This latter view is corroborated, to a great extent, by the analysis of meteorites. Those who maintain that the fall of meteorites is due to gravity alone, must also believe that the proportions of iron and nickel to other kinds of matter in surrounding space is far greater than we know it to be on the earth's crust, and that the earth attracts only iron and nickel because it has nothing else to attract. The presence of hydrogen gas in some specimens of meteoric iron may be explained by supposing that the iron in question originally contained within its substance a minute amount of water, and that as it became heated by passing into the earth's atmosphere, this water was decomposed. The oxygen, under these circumstances, would unite with the iron to form black oxide of iron, and the hydrogen thus set free would be retained within the pores of the softened iron in a highly compressed state, as was the case with that found by Graham in the meteoric iron of Lenarto.

If the amount of hydrogen so liberated were very great, the heated mass would explode and split up into a number of smaller meteorites. This explosion of meteorites has also been observed.

6th. As far as the magnetic attraction of the earth is concerned, the fall of meteorites would occur mostly in the vicinity of the north and south poles. A large quantity of finely divided meteoric dust descending in this manner into the earth's atmosphere, and becoming ignited therein, might contribute to the phenomena of aurora borealis and australis.

7th. If the magnetic intensity of the earth be liable to secular variation, we should find the ordinary weights, and also the atomic weights, of substances to vary likewise.

8th. If the real atomic weights of the elements, after eliminating the magnetic action of the earth, could be obtained, we should probably be able to observe numerical relations between them of a simpler character

---

* Chemical News, June 14th, 1867.

than can at present be found. They might then prove to be multiples of a unit, without any fractions whatever, in accordance with the idea of Prout, as modified by M. Dumas.

9th. The length of a pendulum vibrating seconds would be different if constructed of a magnetic or of a diamagnetic substance.

ON THE ACTION OF

NITROGEN ON THE SILICIDES OF MAGNESIUM AND CALCIUM,

AND ON A NEW DEGREE OF OXIDATION OF SILICIUM.

BY M. A. GAUTHER.

Silicium possesses but a small affinity for nitrogen, which affinity only becomes manifest near its fusing point. The author considered that the combination might be more easily effected by making nitrogen act on silicide of calcium, and especially on silicide of magnesium, magnesium having itself a strong affinity for nitrogen.

Wöhler's silicide of calcium, heated to a red white heat in a current of nitrogen, increased 5·2 per cent. in weight; but the surface only of the silicide was attacked, a small quantity of nitride of calcium was formed, and the silicium separated. The crystallised silicides of magnesium, when treated in the same way, gives a black mass, which behaves like a mixture of silicide and nitride of magnesium; by the action of water it gives ammonia and magnesia, which dissolves on addition of hydrochloric acid, leaving the silicium pure; thus again, the nitrogen was only fused on the metal.

The author prepared silicide of magnesium by the action of magnesium on fluosilicate of sodium. Place at the bottom of a Hessian crucible a layer of chloride of sodium, melted and pulverised; then a mixture of 7 grammes of fluosilicate of sodium with 2½ grammes of chloride of sodium, and over this mixture 2½ grammes of magnesium in lumps. Cover the whole with melted chloride of sodium, heat the crucible quickly in a good wind furnace; when the reaction, which is lively, abates, leave the crucible in the fire five minutes, then take it away and stir the mass with a clay spatula, cover the crucible, and let it cool. Whilst the crucible is open, part of the magnesium burns in the air, giving magnesia and nitride of magnesium; the metallic button contained in the crucible is more or less rich in silicide of magnesium; when it contains an excess of magnesium, which occurs when the temperature is raised too slowly, this button may be considered as magnesium, and submitted to a new operation. First treat it with water to remove the dross, and then with a cold dilute solution of sal ammoniac, which dissolves the magnesium. Metallic crystals are easily obtained, and the silica may be mechanically separated by rubbing: they generally represent 10 per cent. of the weight of the magnesium used: they are leaden grey, and seem to be regular octahedra. A hot solution of sal ammoniac attacks them, disengaging hydrogen, accompanied by silicated hydrogen, leaving a residue of silica. Hydrochloric acid completely attacks them in the cold, giving hydrogen, silicated hydrogen, and a white residue having the form of crystals, and constituting an oxide of silicium which will be noticed later. The composition of silicide of magnesium is explained by the formula,

Mg_5Si_2 (Si, 41·2; Mg, 58·8 per cent.)

The author takes Si=21; Mg=12. In taking Si=28 and Mg=24 this formula becomes Mg_5Si_3.

The author considers that the silicide to which M. Wöhler assigned the formula,

Mg_2Si (Si, 30·6; Mg, 52·9 per cent.),

was impure and contained silica.

The dross formed in the preparation of this silicide contains another product, crystallised in cubes, insoluble in water, and which is a double fluoride of sodium and magnesium:

NaFl,2MgFl,

which may also be obtained by melting chloride of magnesium with fluoride of sodium in excess, and chloride of sodium. The crystals of silicium which accompany them may be removed by treating them with a mixture of hydrofluoric and nitric acids.

Oxide of Silicium.—This oxide, which is formed by the action of hydrochloric acid on silicide of magnesium, has already been indicated by Wöhler, who had obtained it by the action of hydrochloric acid on the silicide, but he did not give its composition. Prepared with pure silicide, it is perfectly white, and possesses all the qualities indicated by Wöhler. Treated with potash, it disengages hydrogen; heated in a tube, it leaves amorphous silicium, and gives a gas which smokes in the air. It is not attacked by concentrated and boiling sulphuric acid: nitric acid attacks it slowly. Its composition is—

$3SiO_2,2HO$, or $4SiO_2,3HO$.

By operating with the greatest precaution, and by taking care that the temperature does not pass 0° when attacking the silicide of magnesium by hydrochloric acid, hydrated oxide may be obtained, having this composition:

$2SiO_2,HO$.

In taking Si=28,O=16, these formulæ become $3Si_2O_4,4H_2O$; $2Si_2O_4$ and Si_2O_4,H_2O.

According to the author these bodies are very different from the *leucon* of M. Wöhler. Leucon is richer in hydrogen and silicium than the preceding compound; according to MM. Geuther and Sheerer it is a hydrate;

SiO,HO.

Thus it is $Si_2O_2,2H_2O$.

After a discussion, which it would be difficult to resume here, the author concluded that there were four oxides of silicium,

Si_2O, SiO, SiO_2, SiO_3;

Or with Si=28, and O=16: Si_2O; Si_2O_2: Si_2O_4; SiO_2; and for the silicated hydrogen, SiH_2; the silicide, Mg_5Si_2, becomes $Mg_5Si_3=2Mg_2SiMgSi$. He admits that the silicated hydrogen is H_3Si_2, and that the silicide of magnesium, Mg_5Si_2, ought to be regarded as a combination of two silicides,

$$3Mg_5Si_2=4Mg_2Si+Mg_3Si_2,$$

only the silicide, Mg_3Si_2 taking part in the reaction which produces the silicated hydrogen, whilst the silicide, Mg_2Si, gives rise to the hydrate, $_2SiO_2,HO$.

ON THE LOSS OF SULPHURIC ACID IN SALT-CAKE MANUFACTURE.

BY CHARLES R. A. WRIGHT, B. SC.

More or less sulphuric acid is always lost in the process of conversion of sodium chloride into sulphate, through the mechanical effect of the escaping gases in carrying off vesicles of acid and sulphate spirted up;

in the roasters also a portion of sulphuric acid is volatilized as such, especially if so much acid have been added as would be necessary to convert the whole of the sodium chloride into sulphate. The total amount thus lost necessarily varies in different instances, being dependent on the form of pot and roaster used, the mode of applying heat, etc.; and especially on the amount of salt left undecomposed in the salt-cake. When ordinary salt-cake is withdrawn from the roaster, a white cloud or vapour is emitted from it; when the amount of acid originally added is sufficient to decompose all the sodium chloride present, and when the roasting has been carried so far as to decompose from 98 to 99 per cent. of the chloride, the escaping vapour contains mostly sulphuric acid with but little hydrochloric; if more sulphuric acid have been originally added, and the roasting carried so far as to leave only 1 to 1·5 per cent. of "free acid," a good deal of sulphuric acid is given off from the salt-cake on withdrawal from the roaster; whilst, if less than the requisite amount of sulphuric acid have been originally added, so that 4 to 6 per cent. of the sodium chloride remain undecomposed, the vapours emitted consist chiefly of hydrochloric acid.

Some experiments made on this subject by the writer, together with some similar details kindly furnished by different manufacturers, yielded the following results:—

Nature of Furnace, etc., used.	Average per centage of undecomposed salt in the salt-cake.	Approximate amount of sulphuric acid lost out of 100 parts originally used.
1) Open Furnace	0·60	12·6
2) Blind furnace: one pot.		About 6
3) Ditto ditto	3·40	Less than 1
4) Ditto ditto	5·00	1·0
5) Ditto two pots	3·00	2·4

As might be anticipated, there seems to be a greater amount lost with an open furnace than with a blind one; apparently also when salt-cake containing 95 per cent. of available sodium sulphate (*i. e.*, 5 per cent. of sodium chloride, "free acid," ferric oxide, moisture, etc.) is manufactured in blind furnaces, the average amount of sulphuric acid lost is about 2 parts in 100. Such salt-cake will contain about 54·5 per cent of SO_3, and consequently 100 parts of salt-cake will require for its production about $54.5 + 0·02 \times 54·5$ or 55·6 parts of SO_3. Acid of specific gravity 1·591 at 15°C. contains 55·6 per cent. of SO_3 (Bineau); hence a kilogramme of such salt-cake represents a kilogramme of sulphuric acid of sp. gr. 1·591; or 0·68 kilogramme of SO_4H_2.

It may be noticed that in (4), the SO_3 present in the shape of sodium sulphate in the condensed muriatic acid was only about one-sixth of the total amount: hence indicating that the majority was derived from the roaster where the heat would be sufficient to volatilize SO_4H_2 as such; the mechanical transfer of vesicles spirted up, is however evidenced by the presence of perceptible amounts of sodium compounds in the gases passing off from the pot.

ON THE RECOVERY OF SULPHUR FROM ALKALI WASTE.

BY LUDWIG MOND.

Alkali waste, black ash waste, tank, vat, or blue waste, are the different names of the insoluble residue obtained by the lixiviation of artificial crude soda, or black ash, produced by Leblanc's celebrated process for the manufacture of alkali, which, in spite of innumerable attempts to supersede it, still furnishes almost alone the very large quantities of alkali at present consumed, and has undergone hardly any essential change since its illustrious inventor introduced it about eighty years ago. This superiority to all other known processes is undoubtedly, to a great extent, due to the production of the above named waste, on account of the valuable property it possesses of separating completely and easily from the alkali in the black ash by lixiviation. Nevertheless this waste has been always regarded as the greatest drawback to this important manufacture. Every ton of alkali produces no less than 1½ tons of dry waste, and the enormous quantities thus obtained are generally deposited in the neighbourhood of the works, often forming hills of considerable height. In damp weather especially this waste evolves large quantities of sulphuretted hydrogen, that most noxious and most disagreeable of all gases, sadly annoying the surrounding population; and, moreover, the rain and ground-water coming into contact with it dissolve out considerable quantities of yellow liquor containing hydrosulphide and polysulphide of calcium, which poisons the water of all wells and rivers to which it has access. These evil results are altogether due to the sulphur contained in the waste, which amounts to no less than 80 per cent. of all the sulphur used in the manufacture of alkali, and which represents, of course, a very considerable value. All efforts to recover this sulphur by a cheap and simple method, and thus also to do away with the nuisance of the waste, have until lately failed in their object, though a great many distinguished chemists and intelligent manufacturers have for the last thirty to forty years devoted much time and expense to this important task, amongst whom Mr. William Gossage (to whose well known labours we owe so many valuable improvements in the manufacture of alkali) takes again the first place. A considerable number of methods have been described and patented, none of which, however, have overcome the principal practical difficulty of the question,—to treat the large quantities of waste without employing too much labour and too large a plant.

It is only within the last few years that sulphur has for the first time been regularly manufactured from alkali waste, by a process of the author's invention, and so rapid has since then been the progress of this new industry, that at this year's Paris Exhibition no less than seven works exhibit sulphur recovered from waste by three different methods, all of which have been patented in England as follows:—L. Mond, 8th September, 1863; M. Schaffner, 23rd September, 1865; P. W. Hofmann, 9th April, 1866. All these processes are based on the same principle—viz., conversion of the insoluble sulphide of calcium in the waste into soluble compounds by bringing the waste into contact with air in order to oxidise it. Lixiviation of the oxidised mass and precipitation of the sulphur in these liquors by a strong acid, in practice of course muriatic acid.

This principle has already been described by W. H. Leighton, in his patent for improvements in converting sulphate of soda into sub-carbonate of soda, dated October, 1863. He proposes to allow waste to remain in the vats until it heats and gives off smoke, then to lixiviate and to precipitate the sulphur from the liquor thus obtained by muriatic acid. It is, however, not probable that he ever worked his process out, no account of it being found, except that in the Register of Patents. In 1852 W. S. Losh took out a patent for obtaining hyposulphite of soda by exposing waste in heaps to the atmosphere, lixiviating it, adding carbonate of soda to the liquor, and crystallising. This process has ever since been worked very successfully at the Walker Alkali Works, near Newcastle, where about six tons of hyposulphite of soda per week are produced. Being engaged in researches on the different processes for sulphur recovery by Mr. Gossage and others in the summer of 1860, my attention was drawn to Mr. Losh's patent, and I at once started a series of experiments in order to ascertain whether, and under what conditions, a quantity of hyposulphite of lime could be obtained by oxidation of the waste, which would render practicable the extraction of sulphur on a large scale, and its recovery by means of muriatic acid. I soon found out that the formation of soluble sulphur compounds in the waste increased only up to a certain maximum, when sulphur to the extent of about 5 per cent. of the weight of the dry waste could be extracted by lixiviation, and that this quantity decreased by exposing the waste any longer. When these soluble compounds, however, were washed out, the waste oxidised quite as well a second time, a similar quantity of sulphur being obtained again, and this treatment could be advantageously repeated even a third time.

The waste I used for these experiments being lixiviated by a singular method, since abandoned, was, however, so dense that all efforts to oxidise it in heaps, or by forcing air through it, failed, so that I had to expose it in shallow layers on shelves. This process was patented in France in December, 1861, and in England in August, 1862, and sulphur to the extent of 12 per cent. of the waste has been obtained by it in considerable quantities in a German alkali works.

Coming to England, in the autumn of 1863, I very soon found, however, that the enormous quantities of waste to be treated, and the high rate of wages, made this process quite impracticable here, and that the waste produced by the excellent process of lixiviating black ash, in general use in this country, was very likely to allow of a much more simple treatment. I tried again to oxidise it by forcing air through it, and succeeded so well that the time necessary to oxidise and lixiviate the waste, which had previously been six to eight weeks, was soon reduced to 60 or 80 hours, and that manual labour was almost altogether avoided by performing these operations in the same vat in which the waste was produced, without moving the latter. These facts led to a new process, which was patented the 8th of September, 1863, since when there have been no alterations in the main features of the process described in my specifications of that date. In place of the set of four vats generally in use for lixiviating black ash, I employ a set of ten or twelve. All of these are connected by pipes in the usual way, so that the soda liquor runs from the bottom of one vat to the top of the next one, and by special pipes and taps which allow the sulphur liquor to run out of the bottom of each vat to the top of any other vat in the set. Besides this, they are provided with extra taps and shoots to convey the sulphur liquor to wells or setters. The lower parts of all the vats are connected with a fan, capable of producing a a pressure of about 7 inches of water by pipes with dampers, which regulate the quantity of air passing through. A silent fan of Schiele's construction, 20 inches diameter, price £10, propels a sufficient quantity of air for the treatment of the waste resulting from 100 tons of salt-cake per week. Four of the vats are always filled with black ash in the course of lixiviation, the other six or eight with waste to be treated according to my invention. As soon as the black ash is completely spent and the weak liquor well drained off, the connection with the fan is opened. The waste soon begins to heat, the temperature gradually rising above 200° F., and gives off quantities of steam, becoming greenish and afterwards yellow on the top, gets more and more dry, and would take fire if the air was passed through long enough. The period at which oxidation should be stopped, and the passing of air discontinued, so as to give the best results, must be ascertained in each works by experiment, and varies according as much or little hyposulphite in the liquors is desirable. In the beginning of the action, hydrosulphide and bisulphide of calcium are formed, which are afterwards oxidised into hyposulphite. A part of the hyposulphite is again decomposed into sulphur and sulphite, which is very insoluble and cannot be extracted by lixiviation. Carrying the oxidation too far would therefore entail a serious loss. On an average, the time of exposure will be limited to between 12 and 24 hours. The waste is now lixiviated sytematically with cold water, the weaker liquors passing from one vat to the next one in course of lixiviation, so as to obtain only strong liquors, which operation can be easily performed in six to eight hours. When this lixiviation is finished, air is again passed through the waste in exactly the same way as before; the waste is again lixiviated, and the same treatment repeated a third time. The vat is then ready to be cast, and is again filled with black ask. When the operations have been conducted well sulphur equal to about 12 per cent. of the weight of the salt-cakes used in making black ash is obtained in solution from the waste. The waste contains only traces of sulphide of calcium, and is principally composed of carbonate of lime, sulphite and sulphate of lime, which, far from being noxious, make the waste, on the contrary, a valuable manure. In separating the sulphur from the liquors thus obtained, by adding muriatic acid, I met with much more difficulty than I had anticipated from apparently so simple a reaction.

Firstly, I wanted an easy and rapid method of determining the quantity of acid necessary for the decomposition of a given quantity of liquor, which always contains hyposulphite, polysulphide, and hydrosulphide of calcium and sodium. For this end I availed myself of the following method:—

1. The hyposulphite is determined as usual by a standard solution of iodine and starch, after having first separated the polysulphide and hydrosulphide by adding an excess of chloride of zinc, and filtering.

2. To a certain quantity, say 3·2 c.c. of the original liquor, and starch, is added a standard solution of iodine until it turns blue, the liquor is then again decoloured by a drop of hyposulphite of soda solution, and litmus, and a standard solution of caustic soda are added until the liquid is neutral.

The following reactions take place:—

$$
\begin{aligned}
&2CaO,S_2O_2+I=CaI+CaO,S_4O_5,\\
&CaSx+I=CaI+xS,\\
&CaS,HS+2I=CaI+S+HI,\\
&HI+NaO=NaI+HO.
\end{aligned}
$$

Thus the caustic soda corresponds to the sulphuretted hydrogen, the iodine used in the first titration to the hyposulphite, and from the iodine used in the second titration and the two former numbers the calcium present in the form of sulphide is easily calculated.

Using for both titrations 3·2 c.c. of liquor, and standard solutions containing one-tenth of an equivalent per litre, and presuming that the polysulphide is bisulphide only, we have simply to add the measures of iodine used in both determination, to subtract the measures of caustic soda, and divide this number by ten, in order to find the total percentage of sulphur in the liquor, from which the muriatic acid is easily calculated, every 32 of sulphur requiring 36·5 of hydrochloric acid.

Generally, the polysulphide contains very little more than 2 equivalents of S to 1 of Ca, so that this method is also sufficiently exact for the determination of the sulphur in the liquors, for practical purposes.

Though this method has been proved to be perfectly correct by a number of accurate experiments, the muriatic acid, as calculated by it, was still more than was actually required to effect a complete decomposition of the liquor. A number of careful investigations made with the view of explaining this fact, have shown that, contrary to the assertions of all chemical handbooks, the products of the decomposition of hyposulphite of lime by muriatic acid are, comparatively little sulphur and very little sulphurous acid, but principal trithionic acid, and a small quantity of pentathionic acid. The reaction was proved to take place principally according to the following equation:—

$$5CaOS_2O_2 + 3HCl = 3CaCl + 3HO + 2CaOS_3O_5 + 4S.$$

On boiling, the trithionate of lime is decomposed to sulphate of lime, sulphur, and sulphurous acid. The latter transforms a portion of the hyposulphite, which is still in the liquor, again into trithionate, according to the well-known equation:—

$$2CaOS_2O_2 + 3S_2 = 2CaOS_3O_5 + S.$$

The newly-formed trithionate is again decomposed, and so on. In consequence of these reactions it is possible to decompose a solution of hyposulphite of lime completely into sulphur, sulphate of lime, and very little sulphurous acid, by adding to it when boiling a quantity of muriatic acid sufficient to neutralise about one-half of the lime in solution.

In places where hydrochloric acid has a comparatively high value, these facts may be taken advantage of. As, however, at the present moment, fully one-half of the acid produced by the decomposition of salt is run into the rivers, or passes into the air, and as, besides, the above-quoted reactions involve a very heavy loss of sulphur in the form of sulphate of lime, and produce also a very impure sulphur, I prefer the following plan, which avoids these inconveniences.

The oxidation of the waste is regulated so as to obtain a liquor, which contains as nearly as possible to every equivalent of hyposulphite, two equivalents of sulphide. This liquor is decomposed by first adding to a certain small quantity of acid an excess of liquor, until there is a trace of sulphide in the mixture; then a quantity of acid sufficient to neutralise the whole of the calcium is poured in, a new quantity of liquor equivalent to this last quantity of acid is added, and then acid again, and liquor again, and so on, until the vessel is nearly filled. To the last liquor only one-half of the required acid is added, and steam introduced, until the liquid shows a temperature of about 140° F. Practically speaking, the liquor and the acid are poured at the same time into the decomposing vessel in nearly equivalent proportions, the workmen taking care to keep a small excess of liquor up to the end of the operation. This part of the process is carried on in wooden tanks covered in and connected to a chimney, in order to carry off any sulphuretted hydrogen which may be evolved by mistake of the workman. If properly carried out there should be, however, no appreciable quantity of that gas evolved.

The practical result of this mode of working is simply precipitation of nearly the whole of the sulphur in a pure state.

$$CaO,S_2O_2 + 2CaSx + 3HCl = 3CaCl + 3HO + (2 + x)S$$

The details of the reaction, are, however, very complicated, almost all the different acids of sulphur being probably formed during the process.

In the first place, by adding liquor to acid, some sulphuretted hydrogen is given off (which may be avoided by starting the operation with liquor rich in hyposulphite) and hyposulphurous acid is set free, which will give rise to the formation of sulphurous and several thionic acids. All these are, however, again converted into hyposulphite by the sulphide of calcium in the liquor, then added in excess.

$$3SxO_2 + 2CaSy = 2CaO.S_2O_2 + (3x + 2y + 4)S.$$
$$3SxO_5 + 5CaSy = 5CaO,S_2O_2 + (3x + 5y + 10)S.$$

The muriatic acid entering next, thus only produces hyposulphurous acid, and its products of decomposition, which are again converted into sulphur and hyposulphite without the formation of any gaseous product, and so on. At the end there is a certain quantity of hyposulphite left in the liquors, which is decomposed into sulphate and sulphur by adding an insufficient amount of muriatic acid. In practice about 90 per cent. of the muriatic acid, calculated according to the above described method, are required to effect thus the complete decomposition of a well-proportioned liquor. If it contains more hyposulphite than above indicated, less acid is, of course, to be used. About 90 per cent. of the sulphur contained in the liquor is precipitated in an almost pure state, and settles exceedingly well within two hours. The supernatant clear solution of chloride of calcium is then drawn off, and another operation directly commenced in the same vessel. As soon as a sufficient quantity of sulphur is collected in it, which will depend on the size of the vessel and on the strength of the liquor (varying from 4 per cent. to 7 per cent. of sulphur), it is drawn out by means of a door at the lower part of the vessel into a wooden tank with a double floor, where the chloride of calcium is washed out by water, and the sulphur then simply melted down in an iron pot. The product thus obtained contains only from $\frac{1}{10}$ per cent. to 1 per cent. of impurities, and is thus by far superior to any sort of brimstone in the market, though it has sometimes a rather darker colour caused by traces of sulphide of iron, or a little coal dust, which latter may have been suspended in the muriatic acid.

The total yield of sulphur obtained by the process amounts thus to 10 or 11 per cent. of the weight of the salt-cake used in making black ash, or about $\frac{1}{4}$ of the sulphur therein contained, and to about 60 per cent. of the sulphate contained in the waste. I still hope, however, to be able to increase this quantity considerably by some more years' experience. The cost of production, as well as that of the plant, are inconsiderable. In the different continental and English works, where the process has now been working for years, the expense for wages, fuel, and maintenance amounts only to £1 per ton of sulphur, and the outlay for the plant has been more than covered by the net profits of the first year.

- *c.* Substances nearly free from sulphides or arsenides, but containing chlorine, iodine, or bromine.
- *d.* Argentiferous litharge, and other easily reducible oxides.

I. A. Metallic Alloys capable of direct Cupellation.

a. Consisting chiefly of Lead or Bismuth.—In determining the silver contained in these alloys, it is only requisite to place a clean piece of the same, weighing about from one to ten grains according to its probable richness in silver, upon a cupel of coarse bone ash, and proceed by concentration and cupellation exactly as has been already described under these heads.

Should the substance be not altogether metallic, or not free from adherent slag, earthy matter, or other extraneous matter, it should previously be fused on charcoal with a little borax in the reducing blowpipe flame, and the clean metallic globule then removed from the charcoal, and treated as before. In order to remove the globule from the inherent borax-glass, it may be allowed to cool, and then detached; or, after a little practice, it will be found easy, by a quick movement of the charcoal, to cause the globule still melted to detach itself completely, and drop on the anvil in the form of a single somewhat flattened globule, without suffering any loss of lead adhering to the charcoal.

In the case of argentiferous bismuth alloys the process is carried on in all respects the same as if silver-lead were being treated. As, however, the bismuth globule is very brittle, care must be taken when separating the concentrated globule from the litharge, as, if not carefully done, a loss may easily be sustained from a portion of the globule remaining behind adherent to the litharge. It is better, therefore, to remove the litharge by degrees from the globule with the aid of the forceps.

Argentiferous bismuth, free from lead, when cupelled alone, invariably leaves a globule of silver, having a dull frosted surface. If, however, at the end of the operation a small quantity of lead (¼ to ½ a grain) be added, and fused along with it, the silver globule then obtained will be perfectly bright and free from all bismuth.

In the case of native bismuthic silver it is advisable to fuse the previously weighed mineral with a little lead and borax-glass on charcoal in the reducing flame, so as to free it from any adherent earthy matter, and then proceed by concentration and cupellation, as before described.

Silver Assay.

I. A. Metallic Alloys capable of direct Cupellation.

- *b.* Consisting chiefly of silver: native silver, bar, test, and precipitated silver. retorted silver amalgam, standard silver, silver coin, and other alloys of silver with gold and copper.

These alloys may be at once fused with lead on the cupel itself, and the operation finished as before described. In general, however, it is better to fuse the weighed assay previously with the requisite amount of pure lead and a little borax-glass, say from a quarter to half the weight of assay, in the reducing flame at a low heat on charcoal until the globule commences to rotate. This ensures having a perfectly clean button of silver-lead, which is then cupelled in the ordinary manner.

In most cases the quantity of lead to be added need not exceed that of the weight of the alloy, but when several percentages of copper are present in the assay, as in case of many coins, etc., the lead should be increased to some three, or even five times the weight of the assay in proportion to the amount of copper actually contained in the substance under examination, and which will be treated of more at length under the head of copper-silver alloys.

When no more lead has been added to the assay than its own weight, the cupellation may be concluded in one operation by inclining the stand, and so moving the globule on to a clean part of the cupel; but when more copper is present, it is preferable to concentrate first and cupel subsequently, in order thereby to reduce the cupellation loss to its minimum.

In the concentration as much copper as possible should be slagged off with the lead, which is effected by inclining the cupel somewhat more than usual. so that its surface may be less covered up with the litharge and exposed as much as possible to oxidation, by which means the litharge, as it forms, is enabled to carry off more of the copper contained in the silver lead.

Should the silver globule after cupellation show indications of still containing copper, as before noticed, when treating of cupellation, a small quantity of lead must be fused along with it, and the cupellation finished as usual.

As at the present time no means are known by which silver can be separated from gold by the use of the blowpipe, in all cases of alloys containing gold, this metal remains to the last along with the silver, and the result in such cases always indicates the combined weight of both these metals contained in the alloy under examination. The employment of the humid assay must be resorted to for effecting their separation:—

- *c.* Containing chiefly copper: native copper, ingot, wire, or sheet copper, cement copper, copper coins, copper-nickel alloys.

Under the most favourable conditions in cupellation, the amount of lead requisite when converted into litharge to slag off one part of copper along with it as oxide, amounts to between seventeen and eighteen parts its weight. In the blowpipe assay it is usual to add to any cupriferous alloy an amount of pure lead equal to twenty-times the amount of copper contained in the alloy, in order to ensure the whole of the copper being separated in the litharge. In the case of nickel the amount of lead required is somewhat less than with copper, but in practice the same amount of lead may be employed.

When the copper is quite clean the requisite amount of lead may be added to it in a single piece on the cupel, fused and cupelled as usual, after previous concentration of the silver-lead to a small-sized globule.

It is generally found, however, that traces of iron, slag, gangue, or other foreign matter is present; and, consequently, it is usually advisable to fuse the assay along with the requisite amount of lead, and about one-half its own weight of borax-glass in the reducing flame, until the whole of the substance is seen to have perfectly combined or alloyed with the lead, and the globule has come into brisk rotation, whilst at the same time no detached metallic globules are seen in the borax-glass.

The concentration of the silver-lead and cupellation are then conducted as usual, taking care when concentrating to incline the cupel-stand so as to expose as much of the metallic surface of the melted globule to the oxidising action of the air as possible, with a view of enabling the litharge whilst forming to carry off as much copper along with it as possible.

Should the silver globule obtained after cupellation spread out, or appear to the eye more flattened than usual with globules of pure silver, it indicates that some copper still remains, and a small piece of assay lead (½ to 1 grain weight) should be placed alongside it whilst still on the cupel, fused together, and the cupellation finished on a clean part of the same cupel as usual.

Precipitated or cement copper, especially that which is in the crude state, and has not been melted and run into ingots, is often very impure, containing so much iron, lead, arsenic, earthy matter, etc., as not to admit of direct cupellation, and in such case should be treated as pertaining to class B. *a.*:—

B. Metallic Alloys incapable of direct Cupellation.

a Containing much copper or nickel, with frequently some little sulphur, arsenic, zinc, iron, cobalt, etc., as unrefined or black copper, brass, German silver, etc.

As the presence of these extraneous matters would interfere with the cupellation either by causing a loss of silver-lead projected from the cupel upon the evolution of the volatile substances present, or by forming oxides which could not be absorbed by the cupel, it is necessary to eliminate such substances by a scorification with borax on charcoal previous to concentration or cupellation.

In the case of unrefined and black copper, the portion used in the examination is placed in the scoop with twenty times its weight of assay lead, and its own weight of powdered borax-glass, mixed with the spatula, and transferred to a soda-paper cornette. It is then fused on charcoal in the reducing flame, which should be constant and uninterrupted, until all particles have completely united, and a brisk rotation sets in, which is kept up for a short time, when the silver-lead globule, which should appear bright on the surface after cooling, is concentrated and cupelled precisely as is directed under A. *c.* By this preliminary scorification the sulphur, arsenic, and zinc are volatilised, and any lead, cobalt, or iron slagged off into the borax-glass.

In the assay of brass and German silver the quantity employed is fluxed with its own weight of borax-glass, but only requires ten times its weight of assay lead. The operation is commenced as before, but the globule is kept somewhat longer in rotation (always keeping the flame directed only on to the borax-glass), so as to allow the zinc present to be completely volatilised, which is evident when the surface of the silver-lead becomes bright, on which the heat is increased for a few moments to expel the last traces of that metal, and the silver lead thus obtained is concentrated and cupelled as before.

The silver globule obtained from the cupellation of substances rich in copper generally requires the addition of a small quantity of lead and re-cupellation (as before described), in order to ensure its freedom from copper.

Behaviour of Lime when Burned.—Dorlhar and Saminn. Two cylinders formed out of the same piece of limestone measured 27 millimètres in length and 17 millimètres in diameter. After being completely burned their volume had increased nearly 1-10th—viz., to 28 millim. and 17·7 millim.—*Berg. und huttimm, Zeitung*, 1867.

NOTE ON THE CALCULUS OF CHEMICAL OPERATIONS.

BY PROFESSOR WILLIAMSON, F.R.S.

The remarkable memoir of Sir Benjamin Brodie, respecting which these remarks are made, is the first consistent attempt to introduce analytical reasoning into the body of the science of chemistry.

One fundamentally important question of method is raised by the memoir; and as it may be considered apart from the rest of the subject, and is, in fact, a preliminary to any discussion upon it, the author wishes to draw attention to some considerations relating to it.

Sir B. Brodie defines a chemical operation as an operation performed upon the unit of space, of which the result is a weight. The unit of matter (or molecule) adopted is the weight of matter of a specified kind, which occupies in the state of perfect gas the volume of one litre at 0°C. and a pressure of 760 millimetres of mercury.

This absolute definition is intended to supersede the prevailing theory that the molecule of each compound is the smallest proportional weight in which we can, consistently with its other properties, represent it as taking part in any reaction, or in which we can suppose it to exist by itself.

In some cases the vapour-densities of many compounds have confirmed the molecular weights assigned to them by a comparison of their reactions; but in other cases, many of which are too familiar to need mention here, the vapour-density contradicts the above evidence of the molecular weight. What is the result in such a case of conflict? Uniformly this: that if the vapour-density and reactions are irreconcileable, we know that the vapour-density must have given wrong advice, and it only remains to be seen by an examination of the anomalous vapour how the molecule broke up on evaporation.

Perhaps the best way to judge of the working of the new definition is to see the manner in which Sir B. Brodie himself applies his principle. Thus, at page 817 of his memoir, the units of thirteen substances are given, and opposite each formula is given the "absolute weight in grammes" of a litre of the vapour, and in another column the "relative weights" of each. Of these fundamental statements four only—viz.: the numbers for sulphur, sulphuretted hydrogen, sulphurous acid, SO_2, and sulphuric acid, SO_3, are the records of observations. The numbers for three other substances are at variance with observation, for SO_3H_2 breaks up on evaporation into SO_2 and H_2O, forming a mixed vapour of about half the density given. SO_4H_2 breaks up similarly, forming a vapour of about half the specific gravity assumed, and Nordhausen acid first breaks up into SO_3 and SO_4H_2, and this hydrate decomposes at a higher temperature, as above mentioned. The vapour from Nordhausen acid has, therefore, a specific gravity vastly below that assumed. No doubt there are good reasons derived from a study of other facts for believing that these three compounds, *if they were capable of evaporating undecomposed*, would have the vapour densities assigned to them by Sir B. Brodie; but taking the simple definition as given, we are led to molecular weights, which the author, in common with all chemists, considers inadmissible, and which he very properly corrects.

seems to be every reason to believe was constructed in 1675. Papin became Boyle's amanuensis in 1676, and remained for some length of time in his service, during which he conducted a number of experiments at Boyle's suggestion, chiefly with a view of testing the accuracy of previously made experiments: these were published, together with a description of the new air-pump, in 1680, in a work written by Papin,[*] but read over and revised by Boyle, whose name alone appears on the title-page. It was written in French, and translated into Latin before printing; a translation into English was subsequently published.

It commences with a description of Papin's double-barrelled air-pump, which consisted of two vertical cylinders of brass, in each of which worked a piston fitted with a valve opening upwards; at the bottom of each cylinder there was also a valve opening upwards; indeed the pump was precisely similar to that used in the present day as regards the fitting with self-acting valves, and only differed in the mode of working the pistons. At the top of each piston rod a metal stirrup was fixed, and these were connected by a cord passing over a pulley. The pump was worked by a man who, putting one foot into each of the stirrups, threw the weight of his body first upon one piston and then upon the other; thus the action somewhat resembled that which is practised on a tread-mill. The advantages of the double pump barrel over the single barrel are considerable: in all the previous air-pumps the piston had to be drawn from one end of the barrel to the other against the whole pressure of the atmosphere, but by the introduction of two barrels, and the connection of the piston rods, so that the descent of one piston caused the ascent of the other, it will be perceived that the pistons balance each other, for the downward pressure of the atmosphere upon one, balances the pressure tending to press down the other. Thus a double-barrelled air-pump not only exhausts in half the time required by a single-barrelled pump, but requires less force to work it.

The degree of rarefaction which obtained in the receiver was measured by a mercury gauge enclosed within the receiver. It consisted of a graduated tube sealed at one end and filled with mercury, with the exception of a small space occupied by a bubble of air, by the expansion of which the degree of rarefaction was ascertained.

The first experiment is dated July 11th, 1676, and relates to "several waies used to help the production of air." The work, for the most part, treats of the preservation of edibles in vacuo, and the amount of air produced by various substances when kept for a length of time in closed vessels. There is nothing of interest or utility among the experiments, which much resembles those described in Papin's former treatise.

Among other things, we find an account of Papin's wind-gun and of some experiments made upon animals in compressed air. A mouse was placed in the receiver of the gun, and the air rapidly compressed to one-twentieth of its former volume, the gun was then discharged, the receiver opened, and the mouse was found to be dead, at which Papin expresses great surprise, as he expected to find it "only a little convulsive." A second mouse was then placed in the receiver, and the air compressed to one-fourth its original volume. On discharging the gun and opening the receiver, the mouse was found to be alive and well. Finally, a mouse was left in air compressed to one-seventh of its volume for 24 minutes, and the gun then discharged. When the mouse was taken out it was observed "to fetch many deep groans," and soon after it died, from all of which experiments he deduces the corollary, "That a great compression of air is noxious, yea mortiferous to animals."

In 1684, Papin was appointed curator to the Royal Society with a salary of £30 a year, for which he was to show at least one experiment at each meeting of the society. It will be borne in mind that this office had previously been held by Hooke, now one of the secretaries to the Society.[*]

In the *Philosophical Transactions* for 1686, we find a paper entitled, "An Account of an Experiment shown before the R.S., of Shooting by the Rarefaction of the Air," by Dr. Denys Papin, R.S.S. Otto Von Guericke had previously described a similar invention, but Papin's gun was considered more effective. It consisted of a long tube fitted with suitable valves. It was exhausted by an air-pump, and the external air was suddenly admitted. By this means a bullet weighing two ounces was propelled with great velocity to a considerable distance.

In the *Philosophical Transactions* for October, in the same year, Papin gives "A demonstration of the velocity wherewith the air rushes into a vacuum." The Academie des Sciences had previously endeavoured to determine the relative velocities of air and water under similar conditions, by filling a bladder first with water, then with air, applying a like pressure, and noting the time necessary to empty the bladder respectively. It was thus found that the bladder of air could be emptied in one twenty-fifth the time necessary to empty the bladder of water, and it was hence concluded that with equal orifices and pressures the velocity of air is twenty-five times greater than that of water. But for many reasons stated by Papin this method is most erroneous. The following mode of demonstration was adopted by Papin. It had been proved that the heights to which dissimilar liquids will be driven by the same pressure will be reciprocally as the specific gravity of the liquids; thus a pressure which causes mercury to rise to a height of one foot will cause water under the same conditions to rise to a height of $1 \times 13{\cdot}5$ feet. From Galileo's demonstration that the velocities of bodies are as the square roots of the heights to which they would ascend, it follows that the velocities of two dissimilar liquids is as the square root of their respective specific gravities. Now the pressure of the air is equal to that of a column of water 32 feet high, which would rush out with a velocity of 45 feet per second. The specific gravities are as 840 to 1, and the roots as 29 to 1; therefore the velocity of air is 29 times greater than that of water under similar conditions; hence he concludes that the velocity of air driven by the whole pressure of the atmosphere, or in other words the velocity of air entering a vacuum, would be $45 \times 29 = 1,305$ feet per second.

Papin continued to act as Curator to the Royal Society till the year 1687, when he was appointed Professor of Mathematics in the University of Marburg, an appointment which he held until his death, in 1714.

Although Papin did not do much by direct means to

---

[*] This work is entitled "*A Continuation of New Experiments physico-mechanical, touching the spring and weight of the air, and their effects.*" The second part. By the Hon. Robert Boyle. London, 1680. The first part of the continuation was published in 1669; an account of it will be found in the thirteenth of these papers, Chemical News, Vol. 12, p. 62.

[*] See the tenth of these papers, Chem. News, vol. ii. p. 38.

further pneumatics, he did much indirect service to the science by the invention and improvement of apparatus. It is strange that the invention of the double-barrelled air-pump should be so frequently attributed either to Boyle or Hauksbee; the error is probably due, on the one side, to the fact that the first account of it was published in a work which claimed Boyle for its author; and in the second place because it was improved and first perfectly figured by Hauksbee, and by him brought into general use. Winkler* of Leipsic, while he is most cautious to mention the slight improvements introduced by Sengwerdus, Wolfius, Leupold, S'Gravesande, and Musschenbroek, does not so much as mention Papin. The air-pump as Papin found it possessed but one barrel; one at least of its valves was worked by hand; and the receiver had to be cemented to the pump-plate before the commencement of each experiment. As he left it, it possessed two pump-barrels, fitted with self-acting valves; a ground pump-plate upon which a receiver with ground edges could remain air-tight without the necessity of cement; and a connection was established between the pistons, so that the descent of one effected the elevation of the other.

We can scarcely be surprised that Papin did not greatly extend our knowledge of the nature and properties of the air, for the above extracts from his works clearly show us that his object was to apply the air-pump to useful purposes, rather than to extend pure pneumatical research. He was prouder of his "Digester of Bones?" than of his double-barrelled air-pump; and he preferred the experiments on the preservation of fruits to the "demonstration of the velocity wherewith the air rushes into a vacuum."

We may mention *en passant*, that Papin was one of the first to adopt the important theory of combustion (since completely verified), of "Ce très subtil Anglois M. Robert Hook," as he calls him.

ON THE

UTILISATION OF THE WASTE PRODUCTS OF THE MANUFACTURE OF COAL GAS.

BY DR. LETHEBY.†

As you are aware, the residual products of gas-making are six in number—namely, *coke*, *ammoniacal liquor*, *coal tar*, and the three waste products from the purifiers, as the *spent oxide of iron*, the *refuse lime*, and the *acid or other matters used for absorbing ammonia*, each of which has its special value on account of its technical uses.

I.—Coke.

This need not occupy much of our attention, as its practical value and uses are pretty well known to you. I may say, however, that it was the opinion of the late Dr. Fyfe, and is still the opinion of many chemists who have examined the power of coal under steam-boilers, that the heat actually made available *in practice* is very nearly the same as ought to be produced *according to theory* by the quantity of coke which the coal yields. He found that a pound of Scotch coal from Trenant would boil away 5·61 lbs. of water, and that the coke of it, which amounted to 0·525 of a pound, produced 3·9 lbs. of steam; so that the practical loss was 5·61 − 3·9 = 1·71 lbs., but the theoretical value of the coke was about 5·5 lbs. of steam. Here is a table of the relative heating power of different fuels, expressed in the number of pounds of water which 1 lb. of the substance will boil away when the water has been heated to its boiling point:—

Dry wood (average of many specimens)	4·51 lbs.
Derbyshire coal (ditto)...............	7·58 "
Scotch coal (ditto)...................	7·70 "
Lancashire coal (ditto)...............	7·94 "
Newcastle coal (ditto)................	8·37 "
Welsh coal (ditto)....................	9·05 "
Good coke (ditto).....................	10·00 "

If all these numbers are multiplied by 5·5, they give the quantity of water which a pound of the fuel will in each case raise from 32° to 212°, and the results show that the thermotic power of coke is very high.

II.—Ammoniacal Liquor.

This is the aqueous portion of the condensed products of the gas. It floats upon the tar, and is a watery solution of carbonate, sulphide, and sulphocyanide of ammonium, with certain carbohydrogens of no value.

If all the nitrogen contained in coal were converted into ammonia, so as to make a liquor of 8-oz. strength (4° Twaddle), it would yield from 142 to 226 gallons per ton of coal. This will be evident from the table which is before you, and which represents the average amounts of nitrogen in certain well-known coals in a dry condition:—

	Nitrogen per cent. in Coal.	Ammonia per cent. from Coal.	Gallons of Liquor of 4° Twaddle p. ton of Coal.
Welsh coal (average)	0·91	1·10	142
Lancashire coal (ditto)	1 25	1·52	196
Newcastle coal (ditto)	1·32	1·60	206
Scotch coal (ditto)	1·44	1·75	226

But by far the largest portion of nitrogen is not converted into ammonia, for by combining with sulphur and carbon it forms the sulphocyanides which are so abundant in ammoniacal liquor and in spent lime, and much of it also unites with carbon and hydrogen to produce the alkaloids which exist in the tar. In practice, therefore, you get but a comparatively small proportion of the nitrogen as ammonia in the ammoniacal liquor. The quantity of liquor rarely exceeds 45 gallons of 8-oz. strength per ton of coals; and to obtain this quantity you must condense well, and also wash the gas with water. I have already explained to you how this is done at the Birmingham and Staffordshire Gas Works by Mr. Hugh Young, who obtains 44 gallons of liquor per ton of Staveley coal in his yearly working. In ordinary practice the yield is about 25 gallons per ton, and in London it is not above 13 gallons—calculated in every case as 8-oz. liquor. You will see from this how largely the production of ammoniacal liquor may be increased; and I will call to your recollection the valuable advice of your president, Mr. Hawksley, with respect to the copious washing of raw gas with ammoniacal liquor, for this practice has a two-fold advantage—it not only purifies the gas by removing tarry matter and sulphur compounds, but it also strengthens the liquor and renders it a more valuable product. By using the liquor as a shower or in a scrubber, in the proportion of 1 volume of liquor to 16 of gas, the liquor may easily be raised to 10° or 11° of Twaddle, which are equivalent to from 20 to 22 ounces of acid; and considering that the price of liquor rises

---

† A lecture delivered before the British Association of Gas Managers. Corrected and communicated to this paper by the Author.

about 4d. or 6d. per butt for every degree of Twaddle, it is manifestly of the greatest importance that the liquor should be sent away from the works as strong as possible. It ought, in fact, never to be under 6° of Twaddle, or of less than 12-oz. strength; and, with proper condensation and judicious washing, there should be from 29 to 30 gallons of such liquor produced from every ton of coals. The average price of ammoniacal liquor of 8-oz. strength, in eleven towns of England, is at the present time 2s. 7d. per butt of 108 gallons. It ranges from 1s. 9d. to 4s. 6d. per butt, and in London it fetches 2s., with an increase of 4d. per butt on every additional ounce of acid strength. Below 3° of Twaddle or 5oz. of acid it does not pay for working, whereas at 10° or 11° of Twaddle it is a valuable product. The strength of the liquor may be estimated either by the hydrometer or by the quantity of strong sulphuric acid (sp. gr. ·1845) required to neutral ise it; and it will be found that every degree of Twaddle is equal to about 2 ounces of acid per gallon of liquor.

The method of converting the liquid into a salt of ammonia varies in different places according to the facilities for working. In some places the liquor is at once saturated either with sulphuric or muriatic acid, in a close tank, and the evolved gases (sulphuretted hydrogen and carbonic acid) are carried to a furnace or to a furnace shaft. The saturated liquor is then evaporated and crystallised in open troughs. This, however, produces a dark-coloured salt which is not very saleable. The liquor, therefore, is either distilled alone from a steam-boiler, or it is mixed with lime in the boiler, so as to fix the sulphuretted hydrogen and carbonic acid, and is then distilled. In many works the liquor is heated in an apparatus called a Coffey's still, which is a tall vessel containing a number of transverse divisions (from 20 to 30) which alternately pass to nearly the opposite sides of the vessel. The liquor is run in at the top, and as it flows from side to side over the alternate divisions, in its way downwards it meets a rush of steam, which is admitted at the bottom of the vessel, at a pressure of from 20 to 30 lbs. upon the inch, and thus the carbonate and sulphide of ammonium are volatilised. In all these cases the ammonia is distilled into a close vessel containing sulphuric acid, diluted with enough water to prevent the salt from crystallising (equal parts of brown chamber acid of commerce and water are good proportions); and the evolved gas (carbonic acid and sulphuretted hydrogen) is conveyed to the furnace fire, or is used for the production of oil of vitriol. When the ammoniacal liquid is evaporated by blowing steam into it, it is necessary to have a worm, or other cooling apparatus, to condense the water from the gases before they are carried to the furnace, or they will perhaps extinguish the fire. While the distillation is going on the acid in the saturating vessel is frequently examined, and when it is thoroughly neutralized, it is run out into a proper receiver, and is then transferred to shallow pans or troughs, where it is evaporated to the crystallising point.

The residual liquor from the stills is not completely exhausted of ammonia, but contains from 3 to 5 ounces of sulphocyanide of ammonium per gallon. It is, therefore, treated with lime, and again distilled, whereby more ammonia is obtained.

If there were a large demand for the sulphocyanide, it might perhaps be worth while to recover it from the spent liquor by evaporation, especially where it could be done by waste heat. Here is some of the residual liquor, and you will notice that when I add to it a very acid solution of a persalt of iron it produces a deep blood-red colour of the ferric-sulphocyanide. Here also is some of the salt obtained from the liquor by evaporation, and it is well suited for the preparation of this white powder, the mercuric sulphocyanide, which is the sole constituent of the little toys called Pharaoh's serpents. Sulphocyanide of ammonium is also used to some extent by photographers. I may here mention that the watery solution which runs from the hydraulic mains with the tar, when the temperature is not below 150° Fahr., contains this salt, without any carbonate or sulphide of ammonium; there is no reason, therefore, why this solution may not be collected, apart from the true ammoniacal liquor which is found in the condensers, for even if it be not of much value on its own account, it might be kept from diluting the liquor in the first stages of condensation, and be afterwards used instead of water for finally washing the raw gas.

In country gas-works, where there is little or no sale for ammoniacal liquor, it would not be difficult to convert it into sulphate of ammonia, by transferring it to an old boiler, then blowing steam into it, and carrying the vapors into a properly constructed vessel, charged with the brown sulphuric acid of commerce, diluted with the mother liquor of a previous crystallisation. In this way every ton of coals should yield about 30 lbs. of sulphate of ammonia.

This sulphate is worth from £12 to £14 per ton, and it is not merely used for agricultural purposes, but it is the salt from which all other preparations of ammonia are obtained. Distilled with quick-lime it yields pure ammonia, which by condensation in water forms the liquor ammoniæ of commerce; distilled with chalk it makes carbonate of ammonia; and it has other applications. There are good reasons, therefore, why great pains should be taken to recover all the ammonia of gas-making. We shall presently see how this may be further accomplished by means of absorbent agents placed at the end of the purifiers.

III.—Coal Tar.

This is a very complex liquid, for it contains at least three classes of compounds—viz., acids, neutral bodies, and alkaloids, the composition and leading properties of which are as follows:—

Acids of Coal Tar.

Names.	Formulæ.	Specific Gravities.	Boiling-points (Fahr.)
Acetic..........	$C_4\,H_4\,O_4$	1062	243°
Butyric.........	$C_8\,H_8\,O_4$	973	314
Carbolic........	$C_{12}H_6\,O_2$	1065	370
Cresylic........	$C_{14}\,H\,\,O_2$	—	397
Phlorylic... ...	$C_{16}H_{10}O_2$	—	424
Rosolic.........	$C_{24}H_{12}O_6$	—	—
Brunolic.......	?	—	—
Neutral Bodies of Coal Tar.			
Alliatous oils....	?	?	?
Benzole.........	$C_{12}\,H_6$	850	177
Toluole.........	$C_{14}\,H_8$	870	230
Xylole..........	$C_{16}\,H_{10}$	867	164
Cumole.........	$C_{18}\,H_{12}$	870	299
Cymole.........	$C_{20}\,H_{14}$	861	341
Naphthaline	$C_{20}\,H_8$	1153	428
Anthracine	$C_{28}\,H_{10}$	1147	572
Pyrene..........	$C_{30}\,H_{12}$	—	?
Chrysene........	$C_{24}\,H_8$	—	?

Basic or Alkaline Bodies of Coal Tar.

Pyridine	$C_{10}H_5\,N$	986	242
Pyrrol	$C_8\,H_5\,N$	1077	272
Picoline........	$C_{12}H_7\,N$	961	271
Lutidine........	$C_{14}H_9\,N$	946	310
Collidine.......	$C_{16}H_{11}N$	937	354
Parvoline......	$C_{18}H_{13}N$	—	370
Aniline.........	$C_{12}H_7\,N$	1080	360
Toluidine......	$C_{14}H_9\,N$	—	388
Xylidine.......	$C_{16}H_{11}N$	—	418
Cumidine	$C_{18}H_{13}N$	952	437
Cymidine	$C_{20}H_{15}N$	—	482
Chinoline	$C_{18}H_7\,N$	1081	462
Lepidine	$C_{20}H_9\,N$	1072	510
Cryptidine	$C_{22}H_{11}N$	—	525

The general properties of coal tar, as well as the proportions of its several constituents, vary with the quality of the coal used, and with the temperature at which it is distilled or carbonized. The tar which is produced from common gas coals at rather high temperature is always heavier than water (sp. gr. 1120 to 1150). It dries freely in the air, and its hydrocarbons are so rich in carbon that the tar cannot be burnt in an ordinary lamp. But the tar which is produced from cannel coal at lower temperatures is lighter than water, and does not readily dry when it is exposed to the air. Besides which, its hydrocarbons are comparatively poor in carbon, and may be burnt in lamps. There is almost every variety of coal tar from these two extremes, but the tars of commerce are chiefly of three kinds—viz., the rich cannel coal tar of Scotland; the tar which is produced from common coal in country gas-works, where the temperatures are generally low; and the still heavier tar of the London gas-works, which is produced at excessively high temperatures. The yield of tar per ton of coals is from 9 to 15 gallons—the latter being the average at country works; and the former, or from that to 10 gallons, is the yield in London, where the tar is undoubtedly affected by the high temperature of the retorts, for it is not only small in quantity, but it is deficient of naphtha, and contains more pitch than country tar; besides which, the dead oil from it is always overloaded with naphthaline.

In London the distillation of coal tar is always effected in stills, which are placed over a fire, and the products are collected at different stages of the distillation. Up to a temperature of from 160° to 190° Fahr. little or nothing flows over, but at that temperature ammoniacal liquor, with *crude naphtha* of a gravity of 850, begins to distil. These continue to flow until the thermometer rises to from 310° to 340°, when a heavier naphtha of a gravity of about 920 is carried over. This is called *light oil*, and it is collected separately until the temperature rises to from 370° to 400°, and then the oil begins to have the gravity of water; after that, and up to the temperature of from 690° to 700°, the oil which is collected is heavier than water, and is therefore called *heavy oil* or *dead oil*—the last runnings having a gravity of about 1060 or thereabouts. If a soft pitch is wanted the process of distillation is stopped at this stage, but if a harder pitch is required it is pushed a little further, and the *green oil* which flows over is rich in neutral oils, which are well suited for making railway grease.

A still containing 2,500 gallons of coal tar will in this way yield about the following proportions of the several products:—

Ammoniacal liquor from	50 to	70 gals.	(average) 60 gals.
Crude naphtha........	30 "	50 "	" 40 "
Light oil.............	12 "	35 "	" 30 "
Creosote or dead oil...	689 "	740 "	" 720 "
Pitch	8 "	10 tons	9 tons.

Each of these products has its commercial value, the naphtha and light oil being used for the production of benzole and toluole of commerce—naphthas which are largely in demand for the manufacture of coal-tar colours.

Formerly the greatest value was attached to the naphtha or benzole which had a low boiling-point, and the contracts, especially with the French, were for a benzole or naphtha which yielded 90 per cent. of volatile oil at a temperature not exceeding 212°, and I have examined thousands of gallons of this quality for the French market. Even at the present time there is a demand for this, which is called 90 per cent. benzole, for making certain aniline reds; and to obtain it the crude naphtha, or the first runnings from the tars, were distilled alone. At present, however, there being a demand for a less volatile oil, the practice is to mix together the crude naphtha and the light oil, and to subject them to fractional distillation, thus:—Steam is blown into them at a pressure of from 20 to 30 lbs. on the inch, and the naphtha which comes over with the steam is called *once run naphtha.* This is purified by shaking it with strong sulphuric acid (sp. gr. 1845), using the acid in small proportions at a time, for fear of injuring the naphtha, and washing with water between each operation. In this manner, after using about 5 per cent. of acid (or ½ lb. to each gallon of naphtha), the brown colouring matter of the naphtha and all basic compounds are either destroyed or removed, and the brown naphtha, after being well washed with water, is again distilled by blowing high-pressure steam into it, and the products are collected at three stages; that which comes over first is called *crude benzole of* 80 *per cent. strength*, the second runnings are a naphtha containing 50 *per cent. of benzole*, and the third is a naphtha which is used for solvent purposes. With the view of strengthening the 50 per cent. benzole, and making it 80 per cent., it is redistilled from a vessel with a steam jacket, whereby the temperature can be regulated. That which flows over at a temperature up to 210° is set aside as 80 *per cent. benzole;* that which distils between 210° and 260° is called 30 *per cent. naphtha;* and the residuum, on being treated with high-pressure steam, yields *solvent naphtha.* Once more the 30 per cent. naphtha, or that which has flowed over at from 210° to 260°, is distilled with a dry steam heat, and when the thermometer has risen to 106° there is obtained a little more 80 per cent. benzole; after which, and up to 234°, there flows over what is called 40 per cent. naphtha, and from 234° to 260° a little of the 30 per cent. Steam is then blown into it, and it yields a little more of the solvent naphtha.

In this way, by a series of fractional distillations, the washed naphtha is made to yield at each successive operation a quantity of 80 and 40 per cent. naphtha. All the 80 per cents. are then mixed together, and are once more distilled by a dry steam heat. The naphtha which flows over at a temperature up to 204° is called 90 per cent. benzole; that which flows between 204° and 210° is called 80 per cent. benzole, and is again fractionally distilled up to 204°; while the residue, on being treated with high pressure steam, yields a quantity of 40 per cent. naphtha.

Five separate products are thus obtained—namely, 90 per cent. benzole, 40 per cent. benzole, solvent naphtha, the last runnings of the first operation, and the residuum of each distillation. Operating in this manner with a charge of 1,587 gallons of crude naphtha and light oil, there is first obtained 897 gallons of once run naphtha and 56 gallons of the last runnings, the remainder (634 gallons) being a residuum of no value except for mixture with dead oil; and the 897 gallons of once run naphtha yields, after it has been purified with sulphuric acid, 301 gallons of 90 per cent. benzole, 195 gallons of 40 per cent., 237 gallons of solvent naphtha, 12 gallons of last runnings, and 152 gallons of residuum.

The 40 per cent. benzole contains also 50 per cent. of volatile oil, chiefly toluole, which distils over between 212° and 248°. This is the oil which is preferred at the present time for the manufacture of coal-tar colours. The several products which are thus obtained in the distillation of coal tar are upon the table before you, and roughly speaking, the proportions per 10,000 gallons of crude tar and their commercial values are as follows:—

40 per cent. benzole	34·4	gals.,	worth	2s. 4d.	per gal.
90 per cent "	53·1	"	"	2s. 0d.	"
Solvent naphtha	41·8	"		1s. 9d. to 2s.	"
Last runnings	12·0	"	"	0s. 9d.	"
Dead oil	3018·7	"	"	0s. 1d.	"
Pitch	36	tons	"	45s. 0d.	per ton

Before rectification the crude naphtha is worth about 1s. per gallon, and the light oil about 6d., the two together fetching 9d. or 10d. a gallon; and once run naphtha is worth 1s. 6d. a gallon. Two samples of this oil from different distillers yielded by fractional distillation the following percentage of proportions of oil at different temperatures:—

	Sample 1.	Sample 2.
Up to 212° Fahr.	15·0	17·5
From 212° to 248°	44·0	42·0
" 248° to 264°	8·0	8·5
" 264° to 300°	13·0	13·0
" 300° to 320°	5·5	4·5
Residuum	14·5	14·5
	100·0	100·0

The samples therefore in commerce from good markets may be regarded as of pretty uniform quality.

In Scotland the method of distilling coal tar is a little different from what it is in England, and this arises from the circumstance that the Scotch cannels yield a tar which is so rich in the volatile naphthas that it is not altogether safe to distil the tar from a still with a naked fire. The tar, therefore, is first submitted to the action of high pressure steam, which is blown into it until the more volatile products are passed off. In this way from 7 to 13 per cent. of *crude or rough naphtha* is obtained with a gravity of about 930. The residuum is called boiled tar, and is distilled with a naked fire. It thus yields from 6 to 7½ per cent. of a *light oil* called *pitch oil* or *torch oil*, which has a specific gravity of from 973 to 976. The next runnings, which amount to from 27 to 30 per cent. of the boiled tar, are generally heavier than water, and are called *heavy pitch oil*, and they constitute the great bulk of the product.

The several products of coal tar are thus used in the arts:—

Coal tar is itself employed as a rough varnish for iron, and in Scotland the *boiled tar* is extensively used for covering woodwork, etc.

Light oil and crude naphtha are either redistilled for procuring benzole and toluole, as I have already explained, or they are employed for making common black varnish or for burning in naphtha lamps. In this country they are for the most part distilled, but in Scotland they are largely used in a lamp called the *foundry lamp*. It is an enlarged form of a lamp which was patented many years ago by Mr Beale, and it consists of a chamber supplied with naphtha, and having a nozzle or jet for directing a blast of air through it. The chamber is covered with a bell with a large hole in the top of it. When the naphtha is lighted and the bell put upon it, the blast of air forces the vapour of the burning naphtha through the hole in the top of the bell, and thus produces an enormously large volume of flame. The light is equal to at least a dozen gas jets, and the cost of it is said to be a penny a night. It is very generally used in the foundries, the ship yards, and other large workshops of Scotland.

Solvent naphtha is a colourless spirit which is chiefly employed for dissolving india-rubber for waterproofing, and resins or pitch for varnishes.

The *last runnings* are also used for varnishes, for making a superior lamp black called *spirit black*, and for burning in Holliday's lamp, which is the common naphtha lamp of the streets. It is an ingenious contrivance for converting the naphtha into vapour by means of a mass of heated metal, and spreading it out in a star-like form.

I have already alluded to the use of coal naphtha as a means of increasing the illuminating power of common 12 or 14 candle gas, and have shown that with a moderately good naphtha, which yields about seven grains of vapour to every cubic foot of gas, the illuminating power may be increased about 60 per cent. Considering that naphtha is now becoming a drug in the market, from the waning of fashion in respect of coal-tar colours, it may be worth while to encourage its use as a naphthaliser, rather than to yield to the public clamour for cannel gas. I have long thought that gas, as well as water, should be dealt with at the consumers' houses, when in either case it is required to be of unusual quality.

The creosote, or dead oil of coal-tar, is used almost entirely for the preservation of timber, and at the present moment, in the stagnant condition of railway business, it is almost unsaleable. I apprehend, however, that it is valuable as a fuel, and that it will ere long be used in steam furnaces. Already there are several patents for its application in this manner, and experiments are now being conducted at Woolwich with the view of ascertaining its practical and economical capabilities. The contrivances which appear to offer the largest prospects of success, are those which deliver the oil into the furnace in the form of a spray or vapour, by means of a jet of steam or blast of hot air; and it is said that the heating power of the oil is from 2½ to 3 times that of a similar weight of coal.

In applying the oil to the preservation of timber, it is necessary that it should be forced deeply into the tissue of the wood. The method employed by the best operators is to place the timber in large wrought-iron cylinders, and then to exhaust it of air and moisture as completely as possible by creating a vacuum. After a time the dead oil, heated to a temperature of 120° Fahr., and thus made as fluid as possible, is let into the cylinder. Pressure is then put upon it until the oil is forced into the wood with a power of 150 lbs. upon the inch. In about three hours the wood absorbs the prescribed amount of creosote, which, with the best houses, is never less than from 30 lbs. to 50 lbs. of creosote to a load of 50 cubic feet of timber; every cubic foot of timber has, therefore, taken up from 6 lbs. to 10 lbs. of oil.

The preservative power of the dead oil is partly due to the antiseptic properties of the creosote, and partly to its filling up the pores of the wood with an oil which gradually resinifies and excludes air and moisture. Different views are entertained of the quality of creosote which is best suited for this purpose. In the contracts which I have prepared for the Indian railway works, I have prescribed that the creosote should have the following properties:—"It should have a density between 1,045 and 1,055; it should not deposit any crystalline matter at a temperature of 40° Fahr.; it should yield not less than 5 per cent. of crude carbolic acid to a solution of caustic potash of the density of 1,070 (14° Twaddle); and it should furnish 90 per cent. of liquid oil when distilled to the temperature of 600° Fahr." The contracts, which I have lately seen, for the Dutch Government, prescribe that the creosote shall be clear, and shall not deposit more than 40 per cent of naphthaline when cooled to the temperature of 32°, and kept at that temperature for 24 hours. Here are specimens of creosote from country tar which fully realise those properties; but this sample from London tar is almost solid at 32°.

Another use to which dead oil has lately been put is the preparation of a dip for washing sheep. It was patented by Mr. McDougall in 1860, and is made by heating together two parts by weight of dead oil with one of a solution of caustic soda of 50° Twaddle (sp.gr. 1,250) which contains about 15 per cent. of soda; and to this is added one part of tallow, fat, or other saponifiable substance. The mixture which is thus obtained has the appearance of a very dark soft soap, and it is either smeared upon the skin of the animal, or dissolved in water and used as a wash.

The *greasy matter or green oil*, which follows the dead oil in the distillation of coal tar, is used for making railway grease, with resin, oil, etc.; and the pitch which is the residual product of the distillation is largely employed for all sorts of purposes.

(To be continued.)

CHEMICAL PRIZES.

The custom of offering prizes for the successful solution of problems in chemistry, is one which deserves some attention in this country. On the Continent it is not rare to find chemical manufacturers, or directors of large works where a particular operation in testing or analysis has to be performed many times a day, resort to the expedient of publicly offering a prize for the discovery of a process which shall fulfil certain prescribed conditions. This plan has several advantages. In most large chemical works there is one operation which has to be performed almost hourly, and on the accuracy and dispatch of which much money is risked. It is impossible for any chemist attached to the establishment to be acquainted with all the improvements which are being made in a particular process, and his time is generally too much occupied in routine work, to admit of his carrying out the experiments necessary for the working out of minor details. A publication of the difficulty through the agency of a scientific press, is often sufficient to bring forward many good suggestions, and we can point to our own "Notes and Queries" column in illustration of the readiness with which chemists will assist each other in the elucidation of a technical problem.

This plan, however, of asking for advice is obviously of limited use. Although any of our readers would, we doubt not, be willing to give a querist information when he could do so by simply writing a letter to our columns, few would feel inclined to enter gratuitously into an investigation, and occupy their time for some weeks, to solve a technical problem simply for the benefit of a manufacturing firm. Hence the system of offering prizes appears especially appropriate, and in many instances the expenditure of £50 or £100 has secured to the manufacturer an analytical process which has saved the outlay many times in the year.

A prize of 300 thalers has just been offered by the Mansfield Copper Mining Company, Eisleben, for the discovery of a process for the estimation of copper in the Mansfield schist, the following conditions being fulfilled:—The process must not occupy more than five or six hours, including all operations. One person must be able, without much exertion, to finish at least eighteen analyses daily. The differences between the analyses must fall within narrow limits. All the claims for the prize, with full particulars, are to be sent to the Company before the end of December next. The decision will be announced on June 30, 1868, and if any of the processes sent in fulfil the requisite conditions the prize will be forthwith paid, but should several be found which appear eligible, to the best will be awarded 200 and to the second 100 thalers. If, however, no satisfactory process is discovered, it is intended that the prize shall be divided amongst those who have sent in the best investigations on the subject. The successful processes are to remain the property of the Company.

A few months ago we drew attention to the fact that one of the largest and most extensive manufacturers of tartaric acid would give £100 as a reward to any one who would discover a satisfactory method of determining, directly, the quantity of crystallisable tartaric acid present in tartars, in a sufficiently ready manner to be applicable to commercial analysis; the name of this firm has not been made public, but should any of our readers wish to know more accurately the conditions of the prize, they can address a private letter to our office.

It is, perhaps, not premature to mention that in all probability a money prize will shortly be offered through the Chemical News, for the discovery of a somewhat similar process of technical analysis, connected with an important branch of manufacture. The details are now under consideration.

ON THE QUANTIVALENCE OF CHLORINE AND OTHER REPUTED MONADS.

BY JOHN A. R. NEWLANDS, F.C.S.

The difficulties with regard to the formation of certain compounds which have been lately pointed out by Dr. Odling and others, seem to indicate that chlorine and other reputed monads must really possess latent bonds, and be capable of acting as triads, etc., under peculiar circumstances. Thus, in the union of ammonia and hydrochloric acid, the nitrogen acts as a pentad, and, if we regard the hydrogen and chlorine in hydrochloric acid as monads, the hydrochloric acid must be decomposed in order that its hydrogen and chlorine may unite with nitrogen, an element for which they have but slight affinity. On the contrary, if we admit that chlorine may act as a triad (just as iodine does in ICl_3), we may suppose that two of its bonds are latent in HCl, and that on bringing HCl in contact with NH_3 the two latent bonds of the Cl unite with the two latent bonds of the N. Or, we may suppose that the Cl in HCl remains a monad, and that the H acts as a triad having two latent bonds, which on the approach of NH_3 serve to unite it with the two latent bonds of the N. This latter view of the constitution of sal-ammoniac, and similar bodies, is, perhaps, preferable, as it represents the H of the HCl as directly united to the N of the NH_3.

It may be said that if this view holds good regarding the union of HCl and NH_3, it ought to hold good with regard to the union of ethylic iodide, C_2H_5I, with NH_3, and that either the I or one of the five atoms of H in the ethylic iodide acts by virtue of two latent bonds, and so unites itself with the two latent bonds of N in NH_3.

For the purpose of the present communication, I admit, in accordance with the views of Frankland and others, that multivalent elements may have their apparent quantivalence reduced by successive pairs of bonds becoming latent. Thus N is a pentad in NH_4Cl, a triad in NH_3, and a monad in ON_2, and C is a tetrad in CH_4 and a dyad in CO, still N is always a perissad and C always remains an artiad.

These views, however, may be extended by considering it possible for a monad, by the development of two or more pairs of latent bonds, to become a triad, a pentad, a heptad, etc., still, however, remaining a perissad. In like manner we may consider it possible for a dyad, by the development of two or more pairs of latent bonds, to become a tetrad, a hexad, an octad, etc., still, however, remaining an artiad.

So that all perissads may really have the same number of bonds (that number being an odd number), and may differ only by the number of pairs of latent bonds which their atoms respectively possess under ordinary circumstances. Again, all artiads may really have the same number of bonds (that number being an even number) and may differ only by the number of pairs of latent bonds which their atoms respectively possess under ordinary circumstances.

Thus I, which is a monad in KI, becomes a triad in in ICl_3; B, which is a triad in BF_3, becomes a pentad in BKF_4; Pt, which is a dyad in $PtCl_2$, becomes a tetrad in $PtCl_4$, and an octad in PtK_2Cl_6; and Si, which is a tetrad in SiF_4, becomes an octad in SiK_2F_6.

In the. following table certain compounds of the monads with O, etc., are given, which are analogous to the compounds of triads and pentads placed alongside of them. I am aware that too great stress must not be laid upon such facts, inasmuch as the number of atoms of O combining with an element, affords us no absolute proof of its quantivalence:—

H_2O	Cl_2O	K_2O	N_2O
H_2O_2	K_2O_2	N_2O_2	
Cl_2O_3	N_2O_3	P_2O_3	
Cl_2O_4	K_2O_4	N_2O_4	
I_2O_5	N_2O_5	P_2O_5	
$KClO_2$.....	KNO_2		
$HClO_3$.....	HIO_3	HNO_3.....	HPO_3
ICl_3	PCl_3		

This table might easily be enlarged to a considerable extent, but I think the above will be sufficient to render the view probable that reputed monads may, under certain circumstances, play the part of triads and pentads. This is certainly the case with I in ICl_3, and the privilege we accord to I we cannot well refuse to Cl, Br, or even to H itself.

(From our own Correspondent.)

Baron Liebig's Artificial Milk; Death of the Patients.—Liquid Diffusion applied to the Extraction of Cane Sugar.—Effect of Tobacco and Snuff in Impairing Memory.

Paris, July 3d, 1867.

Artificial Milk.—At the last meeting of the Academy of Medicine, M. Giboust, Professor at the School of Pharmacy, read a paper which we cannot help noticing. He called the attention of the medical world to the description given of the artificial milk invented by Baron Von Liebig, and regretted very much being obliged to enter into a controversy with him. After having reminded the assembly of the composition of this milk, and insisting upon the difficulties attending the preparation of such aliments in places where it might be most necessary, such as with wetnurses or small families, M. Giboust added that we have at our disposal a natural product which more nearly resembles human milk than does a mixture of cow's milk, flour, malt, lactate and butyrate of potash. It is cow's milk itself. On an average, human milk contains a little more water, more sugar of milk, less butter and caseine than cow's milk. Thus, by taking the latter, and adding a little sugar and a fifth of its weight of water, we have an aliment, at the disposal of everybody, forming a better substitute for human milk than any artificial compound.

M. Depaul, on his part, declared that he undertook experiments on new-born children, to examine the effects of this artificial milk, the taste of which was, by the bye, less agreeable than that of natural milk. Four children were tried. The first two were twins, and born prematurely. In spite of the care bestowed on them, and the nourishment by the artificial milk, they died in two days. The third, born at full time, weighed 3 kilogs. 370 grammes; the mother was ill. The nourishment given was that of artificial milk. At the end of two days, the dejections became green, and on this day the child perished. The fourth infant, born under the same conditions, and nourished with the same aliment, died after four days. M. Wurtz promised to write to Baron Von Liebig, to obtain more precise details on the preparation of this milk.

Diffusion, by M. Robert of Seelswitz, applied in the East Indies for the extraction of cane-sugar.—Previous to a voyage to the East Indies, he traversed Germany and Austria, with the intention of studying the progress made in the manufacture of beet-root sugar in those countries, and to see how far the method could be introduced into the East Indies, for the manufacture of cane-sugar. This process of extracting the juice of the beet-root by means of diffusion was invented by M. Jules Robert, of the firm of Robert and Co., proprietors of works situated in Moravia. Struck with the simplicity of this process, which with cheap machinery and scarcely any wear and tear, gives a finer and more abundant juice at less cost than the usual process, he consulted M. Jules Robert on the possibility of applying this method to the sugar in the East Indies, and the only difficulty was, that of having a machine to cut the cane into the required lengths, inasmuch as cane, from its hardness, presented greater resistance. A cane cutting machine was constructed at Seelswitz, which was found to work successfully on maize stalks. Four engines were sent to the East Indies, along with a triple evaporator. Up to the time of sending off the samples to the Champ de Mars, 1,500 tons of sugar-cane had been prepared. A steam engine of 12-horse power, four cane cutters, and diffusing apparatus in wood will suffice for 70 tons of sugar-cane. The advantages have been found to be:—1. Less force is necessary for equal weights of cane, to cut the cane into slices than to drive rolling machines. 2. That diffusion extracts a juice purer than that obtained by mills. 3. That diffusion extracts from the same quantity of cane 20 per cent. more juice than by mills, as is proved by the comparison of the weight of the stalks and the residues of the diffusion. 4. As the cane contains less pectose than the beet-root, the temperature can be allowed, without inconvenience, to exceed 50°C. and even to amount to 70°C. This is important, because diffusion is quicker at a higher temperature.

Tobacco.—The Abbé Migne has just addressed a letter to a very honourable director of one of the great seminaries of Paris, condemning the use of tobacco and snuff. This letter furnishes us with an opportunity of relating a fact that is personal to us. Several times in our youth and riper age we have taken up and discarded the use of the snuffbox. In 1861, when writing our mathematical treatises, during our labours with M. Lindelof, for the calculation of variations, and when we commenced the editing of our lectures on analytic mechanics, we used snuff to excess, taking 20 to 25 grammes per day, incessantly having recourse to the fatal box and snuffing up the dangerous stimulant. The effect of this was, on the one hand, the stiffening of the nervous system, which we could not account for; on the other hand, a rapid loss of memory, not only of the present but of the past. We had learned several languages by their roots, and our memory was often at a loss for a word. Frightened at this considerable loss, we resolved in September, 1861, to renounce the use of snuff and cigars for ever. This resolution was the commencement of a veritable restoration to health and spirits, and our memory recovered all its sensibility and force. The same thing happened to M. Dubrunfaut, the celebrated chemist, in renouncing the use of tobacco. We do not hesitate in saying that for one moderate snuff-taker or smoker there are 99 who use tobacco to excess.

F. Moigno.

Artificial Milk; Manufacture of it in England; Analysis Disputed.—Report of the Weights, Measures, and Coins Committee; Official Recommendations.—New process of Evaporation.—Improvements in Electrotyping Copper.

Paris, July 10, 1867.

At the last meeting of the Academy of Medicine two protestations were again made against the artificial milk of Baron Liebig. The first is by M. Boudet. The second objection was raised by M. Poggiale, in the following terms:—Baron Liebig tells us that his artificial milk is manufactured on a large scale in England; that there is an Industrial Company which carries on the business on a large scale. The important point to be considered is, whether this new product differs widely in composition from human milk. Baron Liebig has taken as the basis of his preparation that of a milk analysed by a German chemist, named Haideln. This analysis is very old, and when it was made scientific men were not provided with the means which are now at their disposal; and the results have, therefore, been contested.

Nevertheless, in accepting, and taking for granted the truth of Haidelu's analysis, we observe that in the formula of M. Liebig the plastic elements are represented by 10, and the respiratory elements by 38, instead of 24 required by the analysis of M. Haideln. The composition of the artificial milk thus differs much from the true proportions, and in this respect it is inferior in quality to natural milk. In it the fatty matters are replaced by starch. But glycose, it is well known, gives less heat, and therefore cannot replace advantageously the substances we have mentioned. We may also ask why does Baron Liebig add bicarbonate of potash? this new element gives to the milk a taste far from agreeable. In a word, this artificial milk differs from the natural, by its odour, taste, colour, and chemical composition. We should certainly recommend, in preference to it, milk which is most similar in composition to human milk, namely, cows', goats', and asses' milk.

The Committee of Weights, Measures, and Coins, at the Universal Exhibition of Paris, 1867, have made their official report relative to units of measure and weight. The commission advance the following measures:—The prompt substitution, in all its integrity, of the metric system, for the old systems of weights and measures, as it is practically adopted in several other countries in the west of Europe. This system, introduced and legalised optionally, cannot be at once rendered imperative to the exclusion of every other system. A certain delay is necessary for the change; and the different nations are alone capable of fixing its duration. Let us observe in the meantime that experience in several countries has proved that a too long delay does not have the effect of sensibly facilitating the accomplishment of this task. Thus it is desirable that Governments take, henceforth, the following measures, viz:—

1. To order the teaching of the metric system in public schools, and to require that it should form part of the public examinations.

2. To introduce its use into scientific publications, in public statistics, in postal arrangements, in the custom houses, and other branches of Government administration.

3. The commission does not consider, as appertaining to its mission, the duty of making standards the exact prototypes of those of Paris. The Government of each country will take upon itself the verification of each of these standards.

The commission declares that the present report contains the expression of its deliberations and conclusions. It expresses a wish that different nations will yield to the solicitations of science and the manifestations of opinion.

A new evaporating process is carried on by M. E. Parion, at Wardrecques, St. Omer. This process is carried on essentially by the renewal of the surface of the liquid exposed, in the state of fine division, in contact with the air, or the products of the combustion according as the evaporation should take place, with or without the aid of artificial heat. When the evaporation takes place by the aid of the temperature of the air alone, the liquids are divided into a small shower exposed to the wind and sun. By maintaining them in this state, we obtain in a small space, and one easy to cover when necessary, the same results as the concentrating basins and the graduating buildings give, at great cost, and with a vast extent of land.

In the case of the employment of artificial heat, the waste heat from chimneys of factories is utilised in preference, and in the absence of this any source of heat is employed if the products obtained have a sufficient value to pay the expenses.

The reduced model of the apparatus for evaporating by the aid of artificial heat, is exhibited at the Universal Exhibition class 50, group VI.; moreover, a small apparatus is at work in the annexe at Billancourt.

M. Bouillet has discovered a remedy for a defect in the electro deposition of copper, which is sometimes seriously injurious, viz., its brittleness. He has found that a very small quantity of gelatin dissolved in the bath gives a copper of nearly equal malleability to rolled copper, whereas the pure bath only gives a porous defective metal like cast copper. The relative specific gravities of copper in different states are: cast copper, 8·78; laminated copper, 8·95; galvanic copper, 8·86. Gutta-percha moulds are exclusively used by the firm of Christophle and Co. They are applied, either cold by pressure with a lever, or by the hand. The mould is rendered conductive either by black-lead or silver, reduced from the nitrate by nascent hydrogen.

F. Moigno.

Manufacture of starch, utilisation of the waste.—Phenic acid, its manufacture and properties.

Paris, July 17, 1867.

More than 100 tons of wheat are annually employed in the fabrication of starch in France. M. L. Maiche, of Paris, now proposes to utilise the waste as an aliment.

The best wheat only contains 55 per cent. of starch, while rice of the most ordinary description contains 85 per cent.; maize and buck-wheat also contain a considerable proportion. The difficulty consists in the separation of foreign matters, such as bran, cellulose, gluten, etc., contained in the pulp of the grains. Having isolated small quantities of cellular tissue and other substances, the author found that the specific gravity of these bodies was much less than that of starch.

If raw starch is placed in water, a small quantity of almost pure starch is deposited, but the bulk only falls mixed with the different substances above mentioned; these, although specifically lighter, are relatively more heavy, being much larger than the starch grains. M. Maiche takes advantage of difference of specific gravity, in order to obtain a complete separation; he makes use of centrifugal force, by which the specifically heavier bodies are thrown farthest off. The mode of operation is the following:—A mixture of raw starch and two parts of water is introduced into a sort of drum of copper, turning on its axis at the rate of 1,000 to 1,200 revolutions per minute; as soon as the velocity attains 450 turns, the starch commences to be separated, and collects in a compact mass, adhering to the sides of the vessel; all the impurities remain in the water, in the centre, which is easily drawn off, while the perfectly white and pure starch can be removed in lumps. All amylaceous matters can be treated by this method, and the extraction of the starch which formerly required several weeks, now takes place in a few minutes. The return is much greater, for 100 kilogs. of rice, costing less than 100 kilogs. of wheat, give more than twenty francs worth of starch. There is then no reason for employing, in the manufacture of starch, wheat which gives the best and most nutritious flour, and the chief principle of nutrition of which, the gluten, is almost entirely lost by the process actually employed.

We give an extract from the excellent lecture given at the Society of Encouragement for National Industry, on *Phenic Acid and its Compounds*, by Dr. Crace-Calvert. It is well known that when coal is heated to a low degree in retorts or distillatory apparatus it gives off substances that can be classed into four groups.

1. Gaseous products furnishing light, heat, and motive power.
2. Water containing ammoniacal salts, which can be purified by well-known chemical means, and utilised in agriculture and in the industrial and medical arts.
3. A thick, black, sticky mass of a repulsive odour, to which the name of *tar* has been given, and which passes over along with the above-named products.
4. A solid porous body, known by everybody as "coke," which remains in the retorts.

When tar is submitted to distillation, first water is obtained, then products which pass over with this liquid, but which, lighter than it, float on the surface, and are therefore termed the *light coal oils*. Lastly, there is distilled a compound heavier than water, and consequently called *heavy oil*.

It was about the year 1837 that these heavy oils were first used for the preservation of sleepers according to Bethell's process. M. Farestier, engineer-in-chief of the department of the Vendée, conjointly with M. Marin, engineer, published a very remarkable and very complete work on the creosoting of wood and its preservation for twelve, fifteen, or twenty years from decay and the ravages of water and the teredo. There remains in the retort a substance fusible at the high temperature attained after the oils have passed over. This is asphalte or bitumen, which hardens on cooling. The distinguished lecturer then proceeded to "phenic acid," stating that M. Laurent, the great French chemist, was the first to indicate the method of extracting phenic acid from tar. It consisted in submitting the light coal oils to a partial distillation, and treating by a concentrated solution of potash, the products distilling at a temperature between 160° and 200° C.

In 1847 Mr. Mansfield indicated another method of treating the heavy oils by caustic alkalies, and towards 1856 M. Bobœuf made known his modified process of M. Laurent. This consists chiefly in the use of caustic soda instead of potash, and treating the whole of the light oils, instead of a portion, by Laurent's method; but this only gave an impure acid, yet, in a commercial point of view, it was a progress. Of a similar nature were the products manufactured by Mr. John Bethel, since 1847, under the direction of Mr. Calvert. They were used for several purposes, either for the production of picric acid, or for transforming tannic acid into gallic acid, or for preserving organic substances from putrefaction. M. Bobœuf used it also very extensively for this purpose.

In 1859, M. Marmas, of the firm of Guinon, Marmas, and Bonnet, of Lyons, came to Manchester, and requested Mr. Calvert to furnish a purer picric acid than that hitherto made, showing him, at the same time, a product white and crystalline, which they furnished as a type. Mr. Calvert made new researches, and discovered that the most favourable mode of preparation was not to treat the coal oils with concentrated alkalies; but, on the contrary, to treat impure benzine of commerce, or naphtha, by weak alkaline solutions.

By this means, a blackish semi-fluid product was obtained, a little heavier than water, having a sp. gr. of 1·06, containing 50 per cent. of real phenic acid, and which acid he separated partly by the aid of distillation. After further researches, Mr. Calvert produced white phenic acid in detached crystals, melting between 26° and 27° C. Towards the end of last year he discovered a process by which he produces phenic acid free from all unpleasant taste; and what deserves remark is, that it is as pure, though it is made from coal tar, as if it had been artificially produced by the aid of reactions recently discovered by MM. Wurtz and Kékulé.

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Copyright of the Medals.—An Explanation Wanted.—Awards of Gold and Silver Medals.—Extract of Meat.

In our last communication we felt ourselves bound to express our opinion somewhat strongly regarding some of the more salient and least agreeable of the features of the Paris Exhibition. Grumbling comes so naturally to us English, and is therefore so completely to be expected from a "Special Correspondent," that, feeling a little ashamed to think we had fallen so easily into the conventional groove, we determined to complain no more, but proceed like Hotspur in the *Telegraph* to point out the probable winners. At this moment the following circular was placed before us:—

"*Notice to Exhibitors.—The Medals.*

"The Jurors' Awards, and Medals, and Honourable Mentions will be published in course of a few days, and duly notified to the successful Exhibitors.

"The copyright of the Medal being invested in us by the Imperial Commission, and fully secured for the United Kingdom (13 and 14 Vic., cap. 104, and at Stationers' Hall), we have the exclusive right to publish fac-simile copies of the Medal, as well as to supply all reproductions of the design by every process of printing, photography, embossing, electrotyping, or otherwise.

"Exhibitors, desirous of introducing the medal on their show cards, labels, or other printing, should favour us with instructions immediately on receipt of notice of award.

"J. M. Johnson and Sons,
Sole Concessionaires."

This precious document (precious alike in style and spirit), in one sense is to be received with enthusiasm. Henceforth who shall dare to call us "a nation of shop keepers?" The writer contends that to sell any firm such a monopoly is eminently disgraceful. Every exhibitor then who obtains a Medal or Honourable Mention is to be forced to wait as long for his bill heads, blank invoices, or headed papers, as "MM. the Concessionaires" please, and will also be compelled to pay any price for them they may choose to demand. "MM. the Concessionaires" may, for auhgt we know or care, be absolutely incapable of presuming unduly on their exceptional position; but, if they do not, it will solely be due to their good feeling and moderation. It is more than ever evident that everything connected with the Exhibition is "sold," especially the "Exhibitors." It is generally believed, however, that "MM. the Concessionaires" will not have the resources of their establishment too heavily taxed. "In things gone by we see the archetypes of things that are to come." *Verbum sap.*

One word more; the readers of this Journal will have observed that in its advertisement columns it is not unusual to have illustrations of Exhibition Medals. Is it then to be understood that if any English Firm, after having won a medal, should wish to have a cut of it as a heading to their advertisement, such firm will have to pay a tax to "MM. the Concessionaires"? And are we to understand that in default they will have infringed the rights ". . . . fully secured for the United Kingdom (13 and 14 Vic., cap. 104, *and at Stationers' Hall*)"? We call upon the authors of this wonderful parenthesis to define distinctly the position of advertisers in this matter. If this tax is intended to be enforced it is to be hoped that the English Medalists will refuse to lend themselves to what can only be characterised as a most odious monopoly.

It is with pain that your correspondent has felt called upon, by an absolute sense of duty, to make some of the remarks to be found in this and the last letter. It is desired, therefore, before proceeding with the criticisms upon the contents of the Exhibition, to state that, despite what has been said, the writer is deeply and most favourably impressed with the vast majority of his French experience. Red tape is always red tape; the red tapists, like Talleyrand's fair enemy, have but one defect, they are insupportable. The French *people* in general we cannot speak too highly of. It has been said that the grand old French politeness is disappearing; we deny it. Go where we would, we found not only civility and politeness, but kindness and good feeling. Depend upon it, where English people do not meet good treatment in France, it is because by their insular pride and gaucherie they render good treatment impossible. How often do we hear our countrymen use the idiotic expression, "I do not like foreigners." Your true cosmopolitan does not care whether the man he meets is a foreigner or not; if he behaves well he should receive corresponding treatment. Apologising, as in duty bound, for this digression, we resume our study of the objects exhibited. As we stated in our last letter but one, we shall endeavour to take the cases as they are numbered in the Exhibition Catalogue.

In addition to cod-liver oil, Messrs. Allen and Hanbury, of Plough-court, exhibit Liebig's extract of meat, manufactured in Australia at the establishment of Mr. Robert Tooth, of Sydney, who was the first person in Australia to establish works for the manufacture of this article. Up to the present time at Mr. Tooth's works they only employ beef as the raw material. These works alone produce no less at the present time, than between 8,000 and 10,000 lbs. per month, and the resources of the manufactory are such that they are capable of yielding a much larger quantity than this.

When we reflect that 10,000 lbs. of extract represent no less than 160,000 lbs. of the lean flesh, we are in a position at once to see the amount of work that must be gone through in a short time, in order that so perishable a raw material may not be allowed to spoil.

This extract of meat is so rapidly finding its way into our kitchens, and is becoming so much used as "stock" for soups and as the basis of gravies, that it bids fair to become one of the most valuable of our imports, and it is interesting to see that the idea of concentrating a large amount of nutritious matter in a small compass is being worked out in other directions. Powdered meat is now being imported, and if of really high class quality will probably be used in many cases where the employment of the extract would be inadmissible.

We would earnestly, however, caution the manufacturers of these essences or extracts, and powders, against allowing ever so small a quantity of bad quality to find its way into the market. Such substances are precisely those which people at first are slow to appreciate and adopt, and one or two bad samples, by disgusting the purchasers, will retard the sale within a considerable area.

We are now able to announce that no less than 88 gold, 325 silver, and 400 bronze medals have been gained by Bristol firms, and that 270 of those sources of all despair to exhibitors, viz., honourable mentions, have also been inflicted.

Among the exhibitors of chemical and pharmaceutical products the following have obtained gold medals:—

C. Allhusen and Sons, Tyne Chemical Works, Gateshead, and Newcastle-upon-Tyne, bicarbonate, sulphate, and crystals of soda, alkali, caustic soda, chloride of lime, etc.

W. Gossage and Sons, Widnes, near Warrington, for soaps, and silicates used in making soaps.

The Jarrow Chemical Company, South Shields, for specimens of chemical products.

James Muspratt and Sons, 41, Oldhall-street, Liverpool, for chemical products connected with the manufacture of alkali.

Howard and Sons, Stratford, salts of quinine and other chemicals.

Price's Patent Candle Company (Limited), Belmont Works, Battersea, for candles, night-lights, oils, soaps, and glycerin.

James Young, Chemical Works, Bathgate, Scotland, for solid paraffin, candles, oils, etc.

Johnson, Matthey, and Co., Hatton-garden, for articles in platinum and other precious metals. In this instance there has been an award of what, in University language, may be called a "double first," as they have also received a gold medal in group 6, as well as a silver medal.

It is a most invidious task to criticise awards of medals in these cases. We all know how enraged every exhibitor becomes who does not get a medal. We must remember, however, that, in the first place, many of our best houses, disgusted with the labour, expense, and loss of time entailed by exhibiting, had refused to send anything to Paris. In the next place, there is no doubt that a very large proportion of the chemicals and drugs exhibited were not above mediocrity.

We regret that so much of the small space which is weekly at our disposal has of necessity been spent in discussions not immediately connected with the chemistry of the Exhibition. Now, however, that the awards are given, we hope that nothing further will arise to force us to occupy our letters with matters unconnected with science.

The following firms have obtained Silver Medals:—Bailey, Bewicke, British Seaweed, Calvert, H. B. Condy, Cow, Hill, Denton and Jutsum, Demuth, Field, Gaskell, D. and W. Gibbs, Hopkin and Williams, Hurlet Alum Company, Johnson and Matthey, Knight, Macfarlane, Mander Brothers, Mawson, Ogleby, Parkes, Rose, Smith, Tudor, Walker Alkali Company, Warne, Wilkinson. Bronze Medals:—Adams, May, and Baker (Class 30), Britannia Rubber, Burgoyne, Bush, Calley, Clark, W. Cook and Co., Danley, Davy Yates and Routledge, Day and Martin, Dodge, Garrod, Goodwin, Green, Haas and Co., Hodgson and Simpson, Holland, Hosegood, Huskisson, J. Jarrow, Langton and Bicknells, Lamb and Sterry, Lange and Moselle, Lowe (Manchester), M'Dougal, M'Kay, Mason, Nimmo, J. N. Parker and Co., Pulford, W. Ransome, Rogers, Rumsey, Squire, Stephens, Talbot and Alder, W. Taylor and Co., Turner and Son, Wandle, Waring.

Class 45.—Specimens of the Chemical Processes used in Bleaching, Dyeing, Printing, and Dressing.—Silver Medal:

—Hands, Ripley. Bronze Medal:—Barlow, Dickens, Howe. Honourable Mention:—Whincup.

Messrs. C. Allhusen and Sons, of the Tyne Chemical Works, Gateshead, and of Newcastle-upon-Tyne, obtained a medal in Class II. Section A. for their display in the English Exhibition of 1862, and that they fully sustain their old position is evident from their present exhibition illustrating the manufacture of soda. They show bicarbonate, sulphate, and crystals of soda, alkali, caustic soda, of 60 and 70 per cent., chloride of lime, etc. As we stated in our last, they have obtained a gold medal for the superior quality of their productions.

It is both interesting and instructive to study the mechanical and chemical requirements of one of these colossal chemical manufactories. We all know the enormous space required for vitriol chambers, and the absorption apparatus for making chloride of lime. In addition to this, which alone forms an immense plant, there are actually saw-mills, common and fire-brick manufactories, coke-ovens, and gas-works, besides, of course, an extensive cooperage. Such is the nature of Messrs. Allhusen and Sons' "plant," and they are, we believe, by no means the largest manufacturers of their class. After this we shall not be surprised to hear that their weekly consumption of raw material is as follows:—

Coal	2,250	tons.
Pyrites	350	"
Nitrate of soda	10	"
Chalk	900	"
Salt	450	"
Manganese	100	"
Limestone	125	"

The weekly production of sulphate of soda is 500 tons, equivalent to 375 tons of soda ash or unrefined alkali; which is in subsequent processes converted into quantities varying with the demand, and not exceeding separately 450 tons of crystals of soda, 150 tons refined alkali, 100 tons bicarbonate soda, 30 tons caustic soda, and 110 tons chloride of lime.

So much has been written and said about the soda process, that it is entirely unnecessary to enter upon the subject here, except to say that in spite of the innumerable attempts that have been made to supersede Leblanc's method, it is still adhered to by all manufacturers of soda. It is true that Mr. W. Gossage, of Warrington (whose name has been so long and intimately connected with the alkali manufacture), has devised a new plan which appears to have the germs of success in it; but whether it is absolutely a commercial success, we are not at the present moment aware. This much is certain, that the new process cannot be in the hands of any one more aware of the difficulties lying in the way, or better prepared successfully to encounter them.

Vauquelin a very long time ago endeavoured to take advantage of a reaction which even appears to have been known to the alchemists, namely, that when chloride of sodium is heated to a high temperature in presence of silica and water vapour, hydrochloric acid is evolved and a silicate of sodium formed. The production of soda from this silicate is a problem that has attracted a vast number of chemists, but, up to the present time, unsuccessfully. Tilghmann in 1847, and Fritzsche in 1858, have both attacked the question, but, as far as we know, with no material advantage.

Mr. Gossage subjects the silica to the action of chloride of sodium *in the state of vapour*, and in an atmosphere of steam. This is effected by sending the steam and the vapour of the salt into a large tower lined with fire brick and filled with flints. The silicate of soda flows down, thus exposing a fresh surface of the flint to the action of the vapour. The silicate of soda has to be decomposed by either carbonic acid or lime. The details of this part of the process are not in our possession at present, and from the known difficulties which lie in the way, must be very ingenious and instructive; we hope, however, to be able to lay a complete account before our readers at no distant period.

Mr. Gossage has most deservedly had his labours recognised, he being one of the few English exhibitors of chemical products who have been awarded a gold medal.

Before proceeding any further in our notices of the English exhibitors, we must once more express our deep regret that none of the manufacturers of aniline dyes were represented. When we remember the part that England has taken in the discovery and investigation of coal tar colours, it is almost humiliating to see the brilliant cases of foreign manufacturers, whose only part in the matter has been to infringe our patents, and by deluging the market with cheap, and in most cases inferior colours, bringing the trade to the verge of ruin. This remark, be it understood, is not intended to apply to the French chemists, who, it must be admitted, have treated us with far more justice than our German brethren. We looked in vain for a specimen of the superb Britannia violet of the MM. Perkin, which for two years has been the most successful rival of Hofmann's violets. For a long time its extreme solubility in water (almost as great as ordinary "Hofmann" in spirit) made it stand alone, but we believe that M. Porrier's violet from methyl-aniline is also remarkable in that respect as well as for its brilliancy. A method has been adopted, we understand, for rendering Hofmann's violet soluble in water.

The cases of MM. Perrier and Cheppet Fils, and of the Fuchsine Company are, especially the latter, exceedingly interesting and well arranged, and the more we admired them the more vexed we were to see no rivals to them in the English department, especially when we knew how easy it would have been for Perkin and Nicholson and Co. to have beaten them.

The question has often been asked us, "Did the Fuchsine Company, ever bring out any colour of their own invention?" Perhaps some of your readers will be able to answer this.

The next case in order which we shall notice, is that of Messrs. Samuel Berger and Co., who display specimens of rice starch; but their case, which looks very dull, has only two dishes of starch and seven show cards in it, and therefore simply seems as a foil to the case of J. and J. Coleman, and Isaac Beckitt and Sons. Both those firms gained medals in the English Exhibition of 1862. The starches of all these makers appear of the finest possible quality. Messrs. Coleman and Co., and Messrs. Beckitt and Sons both show coloured starches of various shades. By means of these tinted starches muslins can be "got up" of any desired tint, and ladies can therefore have a muslin dress of a different colour every day, it being merely necessary to wash it and then stiffen with starch of the desired hue. We have been informed by those who have used them, that the results are all that can be desired.

Perhaps some of your readers may be unaware that starch can be dyed with the utmost facility, and without destroying the granules, by merely filtering a solution containing the desired colouring matter through a layer of the starch. When dried at a very moderate temperature, the so-called "starch lakes" are thus produced, and in brilliancy and soft beauty of tone they are perhaps unsurpassed. Unfortunately colours thus prepared have but little "body," and, what is perhaps worse, they are decidedly fugitive. Nevertheless for many purposes where a beautiful "mat" surface is required of velvety texture, they are very useful. Coloured confectionery may be cited as an instance where the starch lakes may be legitimately employed.

Messrs. Isaac Beckitt and Sons have had the wisdom to display, side by side with the coloured starches, muslins of corresponding tint prepared by their use. We would recommend these gentlemen to renew the muslins, and also the coloured starches, at moderate intervals, as they will not stand many months of glaring daylight, without undergoing deterioration.

We are not with certainty aware of the nature of the dyes used by these firms for the purpose of colouring their starches, but all the coal tar colours are admirably adapted for the purpose, as the colour is almost entirely absorbed when cold aqueous solutions are filtered through a moderately thick layer of the starch.

Group V.—Class 44: Chemical and Pharmaceutical Products.—Numbered 7 in the English catalogue (8 in the *Catalogue Général*), we find "Borwick, George, 34, Chiswell Street, London. Baking powder, chemicals, spices, etc.," and we are also referred to p. 132 of the appendix for further details. What can induce any one to exhibit baking powder we are really at a loss to imagine. It certainly is not a subject of any scientific interest, it is not a novelty, it is not interesting in appearance; its mere physical character offers no guarantee of its purity, and, in fact, its negative qualities preponderate so largely, that positively we are astonished that its exhibitor did not (like a great firm of blacking manufacturers) obtain a medal. And yet this baking powder, so insignificant in appearance, so uninteresting in a scientific point of view, so unfit, therefore for exhibition, is measured by a commercial standard, of far more importance than many objects that rivet our attention by their beauty or scientific interest. We have been credibly informed that a fortune has been made by its sale.

Then what is this baking powder out of which fortunes have been, or are to be made? Of the composition of the powder of Borwick we know nothing, but Cooley's powder is as follows:—Tartaric acid, ½ lb.; barcarbonate of soda and potato farina, or British arrow-root, of each ¾ lb. (each in powder); separately dry them *perfectly* by a very gentle heat, then mix them in a dry room, press the mixture through a sieve, and at once put into packets, observing to press it hard, and to cover it with the foil or close-made paper, to preserve it as much as possible from the air and moisture. Delfort's formula principally differs in the addition of *alum!* and carbonate of ammonium. With the addition of a little turmeric the compound becomes the "Egg powder" so often seen in the windows of grocers and oil-men. These mixtures are used in domestic economy as substitutes for yeast in bread and butter in pastry, and are in their way, and in their proper places, useful, although humble adjuncts to the *materia* (may we not say *medica*), of the non-professional cook. There is no doubt that by enabling pastry to be made equally light, and with one-third less butter, the better class of baking powders have prevented many a bilious and dyspeptic attack.

Mr. Borwick, in addition to his baking-powders, exhibits what he terms "ozonised cod-liver oil." We are sorry to find cod-liver oil "repeating" itself in our notices of the chemical and pharmaceutical products in the French Exhibition, but we will not prevent the unsavoury nature of the subject to turn us from our duty. We consider "ozonised cod-liver oil" to be the greatest of the many delusions connected with this useful food—for food it is purely and simply, and the sooner medical men understand its true character the better for their patients.

Mr. Borwick's prospectus states that the impregnation of cod-liver oil with ozone is for the purpose of "conveying artificially to the lungs of the delicate and consumptive, without the effort of inhalation, and in larger proportions than found in the atmosphere, this extraordinary life-giving agent." The prospectus concludes with the following somewhat rash paragraph: "In fact, it is now proved beyond doubt, that ozone is to the weak, delicate, and consumptive, what quinine is to those who are affected with fever—*the nearest approach to a specific yet discovered.*" The italics are those of Mr. Borwick.

Now, it appears to us that this prospectus has certain points of resemblance to the three incompatible pleas anent the cracked pot, viz.: "1st, that it was cracked when we borrowed it; 2nd, that it was whole when we returned it; 3rd, that we never had it at all." For, in the first place, a distinguished chemist who purchased some and examined it, came to the conclusion—1st, that it did not convey ozone to the lungs of the delicate and consumptive; 2nd, that if it did, it was not "to the weak, delicate, and consumptive, what quinine is to those who are affected with fever; and, 3rdly, that it did not contain ozone at all." It is really inconceivable how any one with even a smattering of chemical knowledge could imagine even if the oil *did* contain ozone that it would carry it to the lungs. The trifling fact that the oil has to be digested before it can enter the blood seems to escape the believers in this so-called remedy. That certain oils acquire powerfully oxidising properties on exposure to light and air we admit, but it must be remembered that in all cases yet known the active oxygen attacks the *oil itself* as soon as the temperature is raised, and many even attack other oxidisable substances present at the same time. The most remarkable instance of the oxidisation of essential oil, is, undoubtedly, that of isoprene*; but when ozonised isoprene is distilled (although it boils at about 40°C.) the ozone present attacks the isoprene with violence, and converts it into an oxodised substance. We think, moreover, with the observer of that reaction, that it is doubtful if the oxygen in what we have hitherto termed ozonised oils is really in the state of ozone. The phenomena attending the passage of ozone through tubes of caoutchouc seem to indicate the impossibility of ozone existing (as such) in the presence of oxidisable organic matters.

Even if we admit that consumptive patients are better in an atmosphere which indicates the presence of ozone (or what is assumed to be ozone) what does that really prove? It seems to us rather to show that consumptive people are better when the air is free from impurities incompatible with the presence of ozone, than that the ozone itself is beneficial to them. The reaction indicated by ozone test papers is not the measure of the total quantity originally in the air, but of the residue left after the destruction of the impurities. But enough of this; we trust that the time is fast approaching when medical men will know more, and talk less, about oxygen and ozone. If one did not hear it so often, it would seem impossible, that in these days of education, doctors are still found who tell their patients to go to the sea-side, "where there is *more oxygen* than in the close and confined streets of towns."

The British Sea-weed Company (Limited) Whitecrook Chemical Works, Dalmuir, Glasgow, have an interesting collection illustrating Mr. Stanford's process of treating sea-weeds.

When sea-weed is incinerated in the usual way a great loss of iodine is experienced, amounting, it is said, to no less than half. Mr. Stanford, by distilling the weeds in iron retorts, entirely prevents this loss, and obtains, in addition to a valuable series of products of destructive distillation, a charcoal which, after lixiviation, is well adapted for the purposes for which animal charcoal is generally used. Indeed we are informed that the carefully prepared charcoal, from certain varieties of weed, actually exceed in bleaching power the best animal charcoal to be found in commerce. The extreme porosity of sea-weed charcoal is greatly in its favour for bleaching and deodorising, in fact, so readily does it allow even thick syrups to pass, that the filters seldom or never become clogged, if properly arranged. They exhibit three different kinds of this charcoal; No 1 from "Tangle" is intended for sewage filtration and as a deodoriser; No. 2, from Bardarrie, is at present sold for bleaching; and No. 3, from Black Wrack, is proposed for sugar-refining.

The Company also exhibit iodine, bromine, and potash salts, the latter extracted from the charcoal remaining in the retorts after the distillation is finished. There is also sufficient nitrogen in the sea-weed to yield enough ammonia to figure as an element in the profits of the undertaking. Whether the oils and tar shown are of sufficient value to be of importance in a pecuniary point of view we are not aware. We should like to know whether a *thorough* scientific examination of the acid, basic, and neutral products of the destructire distillation of sea-weed has yet been made, as it would be very interesting to compare them with those from wood and coal, and especially peat.

---

* Phil. Trans. 1860.

It is highly satisfactory to find that the process which was considered by the jurors of the Exhibition of 1862 as sufficiently hopeful and ingenious to deserve a medal, is now carried to a successful issue under the superintendence of its inventor.

REPORTS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 20.

Dr. Warren De la Rue, F.R.S., *President, in the Chair.*

In continuation of our report of this meeting, we have yet several communications remaining to be noticed.

Professor J. A. Wanklyn read a paper on "*Water Analysis; Determination of the Nitrogenous Matter,*" of which Messrs. E. T. Chapman, Miles H. Smith, and himself were joint authors. Referring to the present unsatisfactory state of our knowledge respecting the decompositions and mode of detection of organic matters (and particularly those of animal origin) occurring in potable waters, the authors quote experiments which tend to prove that, by the evaporation test, the quality of an identical (bad) sample of water may appear widely different according to the rate of evaporation and the manner of applying the necessary heat in the process of analysis; and, further, when a sample of water containing urea or other sewage products, is diluted with a known proportion of distilled water the indication of impurity is not diminished in the ratio anticipated. Extracts from the Report on Metropolitan Waters by Drs. Hofmann and Blyth, 1865, and from the Discourse on Potable Waters delivered last year by Dr. W. A. Miller were read as authoritative admissions of this and similar practical difficulties. The authors further state that no reliance can be placed on Pugh's method of estimating nitric acid as ordinarily performed, and that ammonia cannot be determined in waters containing nitrogenous organic matters by any process involving the boiling with an alkali.

Direct experiments were made upon known quantities of urea, albumen, and gelatin dissolved in water, and the singular fact was disclosed that, whilst the first of these bodies is completely changed into ammonia by boiling with *carbonate of soda*, the two latter substances resist decomposition until *caustic soda* (or potash) is introduced, when *one-third* of the nitrogen contained in them is evolved in the form of ammonia. The remaining *two-thirds* of this constituent are finally liberated in the same form upon adding some crystals of the permanganate of potash and continuing the distillation. The authors employ Nessler's test for indicating the proportion of ammonia originally contained as such in the water, as well as that subsequently formed, and they rely upon the before-mentioned ratio as confirmatory of the existence of the nitrogen in this most objectionable albuminoid form. The details of operating are minutely described in the paper, and several examples are given by way of showing the application of the process. Thames water collected at London-bridge on June 18, tide two hours' flood, contained—

	Grains per gallon.
Ammonia (ready formed)	·0980
Urea	·0889
Albuminous matter (equivalent to white of egg)	·8820

Other results are quoted for East London water, New River, Lambeth and Vauxhall, and water taken from the pumps in Berkeley-square and Bishopsgate-street.

The President inquired the reason of its being found necessary to determine the ammonia separately in the distilled products obtained in the second and third stages of the operation. Why not mix these together and proceed to estimate at once the whole of the nitrogen existing in the organic form?

Professor Wanklyn, in reply, said this course might be adopted, but he considered that a valuable indication towards fixing the nature of the nitrogen was obtained by their separate examination, and this did not in practice occupy a longer time.

Dr. Thudichum offered some remarks on the probable applicability of this process to the examination of the "rice-water" evacuations in cases of cholera.

Mr. Dugald Campbell said that his experiences were not in accordance with the statement just now made by Professor Wanklyn. He found that a solution of gelatin invariably gave off part of the nitrogen in the form of ammonia even upon distillation with carbonate of soda, and the results in the case of urea were not decisive, since it required an addition of caustic alkali before all the ammonia resulting from its decomposition could be expelled. Permanganate of potash had been tried by the speaker in the examination of abnormal excreta obtained in a diabetic case, but neither this agent alone, or aided by the addition of the caustic alkali, sufficed to liberate the whole of the nitrogen even when the heat applied was so great as to cause the destruction of the glass vessel.

Mr. E. T. Chapman remarked that when the amount of albumen or gelatin operated upon was found considerable, it was necessary to fill up the retort once or twice with pure water, otherwise the whole of the ammonia could not be obtained by distillation. This precaution might even be required in the examination of any impure water.

Dr. Cook made a short statement in general confirmation of Mr. Campbell's remarks.

The Secretary then read a paper entitled "*Analysis of a Biliary Concretion, and on a New Method of preparing Biliverdine,*" by Dr. T. L. Phipson. The concretion was found in the liver of a pig, and was of considerable size, being about 3 by 2 inches, and of a yellow, waxy appearance. In the natural state it contained 37 per cent. of water, but after pulverisation and exposure to air it lost all but the 8 per cent. shown in the analysis. Duplicate determinations were made of most of the constituents. The gall-stone had the following composition:—

Water	8·00
Cholesterine	1·35
Mucus	11·50
Hyocholate of soda, with some hyocholic acid and hyocholine	2·75
Cholepyrrhine	61·36
Carbonate of lime	1·55
Phosphate of lime	3·25
Soda	1·11
Chloride of sodium	7·13
Caprylic acid, matters not determined, and loss	2·00
	100·00

The principal constituent is the yellow colouring matter, cholepyrrhine (or bilipheine); this, on digestion with alcohol acidulated with hydrochloric acid, passes into solution as biliverdine, which has a bluish-green colour, and may be separated on addition of water. The author's experiments have led him to believe that there is a close analogy between the yellow and green colouring matters of leaves and the bilipheine and biliverdine derived from animal sources. The last named body is said to differ from chlorophyll only by the elements of two equivalents of carbonic acid.

Dr. Thudichum said that the occurrence of gall-stones in the pig was exceedingly rare. He regarded the analogy or identity of chlorophyll and biliverdine as altogether impossible, these substances showing great differences in their optical properties as well as in their composition.

A paper, by Dr. Stenhouse, "*On the Action of Chloride of Iodine on Picric Acid,*" was next read. Referring to a previous communication to the society in which the ultimate products of this action were stated to be chloropicrin and chloranil, the author has now investigated the intermediate hich could not formerly (from the manner of con- e operation) be isolated. Three parts each of picric acid, together with one part of iodine, were into a digesting flask through which a current of s passed, whilst the contents were maintained at mperature for several hours, and until red nitrous menced to appear. The chloride of iodine was ed off and the residue in the retort heated with ater, from which, on cooling, crystals of dinitro- nic acid separated out. Analyses both of this acid e silver salt were made. Its formula ($C_6H_3Cl\,[NO_2]_2$ all its properties coincide with those observed in duct obtained by Griess when acting upon chlorinated phenol with nitric acid.

Dr. Stenhouse treated *Styphnic Acid* in a similar manner, but this gave only chloropicrin and carbonic acid, thus adding further support to a previous statement of the author "that styphnic acid is not, as Erdmann erroneously supposed, merely an oxidated picric acid, but it must have a different nucleus."

The Secretary then gave a short account of a paper, by Mr. Henry Bassett, "*On Julin's Chloride of Carbon.*" Dr. Hugo Müller obtained, in 1864, a white chlorinated product by the action of pentachloride of antimony upon benzol, and gave to it the formula C_6Cl_6, suggesting its identity with the chloride of carbon of Julin, to which Berthelot ascribed the doubtful formula $C_{10}Cl_{16}$. Mr. Bassett has now reproduced Dr. Müller's body by passing chloroform vapour through a red hot porcelain tube. It crystallises in long colourless needles, which are fusible at 231° C., and the vapour density and analytical results were found to correspond to the formula C_6Cl_6.

The President then adjourned the meeting until November 7, as already announced.

ROYAL INSTITUTION OF GREAT BRITAIN.

A Course of Four Lectures on Spectrum Analysis, with its Applications to Astronomy. By William Allen Miller, M.D., F.R.S., *&c.*

Lecture III.

Solar Spectrum.—Methods of Observation.—Constituents of the Solar Atmosphere.—Spectra of the Moon, and of the Planets, Comets, and Meteors.—Inferences.

We approach to-day the most difficult, and what may probably be considered the most interesting part of the subject which I have undertaken to bring before you, the application of the principles of spectrum analysis to the examination of the condition of the heavenly bodies. Our attention will be specially directed to the sun and some of the bodies of the solar system.

In order that I may do this with effect, let me briefly recapitulate the principal facts which I have to make use of—facts which I have endeavoured to bring before you experimentally in the last two lectures.

We shall have to-day to examine the third of the classes of spectra represented in the diagram—continuous bright spectra crossed by dark lines. Now it will be remembered that every gaseous body at a sufficiently elevated temperature, has a specific spectrum. That spectrum may have its brilliancy increased as the temperature rises, and it may have new lines brought out, but it does not lose lines which it exhibits at a lower temperature. We saw that compound bodies, when sufficiently heated, were separated into their components, and that such compound bodies under those circumstances gave rise to the special spectra of their components. In many cases some of these components are of a nature which give feeble spectra, consequently the spectra of these bodies may entirely disappear from the image projected upon the screen, although the spectra of the other constituent is exceedingly plain. Spectra of the transparent elementary gases in particular are amongst those which disappear under those conditions, such as oxygen, nitrogen, and the permanent gases generally. In one or two instances, elevation of temperature brings out in these gases, spectra which differ from those produced at lower temperatures. A new spectrum is indicated at the high temperature, which was not previously discerned. It is supposed that in these cases the change in the spectrum is accompanied by a change either in the chemical or the molecular constitution of the body by which that change is manifested.

Let me now remind you of an experiment which I showed in the first lecture, where we transmitted the light of the charcoal points through the vapour of sodium; but it will depend upon the relative temperature of the two spectra what the effect shall be. If the vapour of sodium is at a considerably lower temperature than the body behind it, which is giving the continuous spectrum, sodium vapour in this case absorbs rays corresponding in the frequency of their vibration to its own. The temperature of the sodium being only slightly raised, the light which it emits will be a little greater than that which the sodium alone would have produced, but it will be considerably less than that which would be produced by the portion of the continuous spectrum, behind, which it has absorbed; and the result is that when the image of this sodium light is thrown upon the screen, instead of having a bright line, we obtain a black line, or what appears to us a black line, that black line being really a line of low illuminating power contrasted with the spectrum of high illuminating power, and therefore producing upon our eyes the impression of a black line. The intensity of that black line will vary with the difference between the temperature of the body behind and that of the sodium by which the absorption is effected.

If the sodium be raised in temperature until it acquires the same degree as that of the body behind it, the light which falls upon the sodium will be absorbed as before; but now as the intensity of the sodium light itself is equal to that of the incident light, we shall have no sensible effect produced. Therefore the spectrum which falls upon the screen will be continuous, if the sodium be at the same temperature and equally luminous with the portion of spectrum which falls upon and is absorbed by it. But if, on the other hand, the sodium be still hotter, and be still more intensely luminous than the body behind it, it will now in its turn predominate, and instead of a black line we shall have a bright line, or a line of increased brilliancy.

Now I wish you specially to bear in mind these three conditions, which may be produced by the incandescent sodium vapour. 1. We may have a black line when the temperature of the sodium is low; or, 2, we may have no sensible effect, in which case the temperature and the light of the sodium are equal to those of the incident light; or, 3, we may have a bright line, in which case the temperature of the sodium and its light are considerably greater than those of the incident light. What is true in these respects of the vapour of sodium is also true of the vapours of all incandescent bodies. We shall see the application of these points very shortly.

Before we go directly to the consideration of the solar spectrum, let us endeavour to acquire some notion, if we can, of this vast centre of force upon which we are dependent every instant of our lives, and upon which the whole frame around us is dependent for the maintenance of its energies.

The sun, then, we must remember, is a vast body at the distance of 95 millions of miles from us, or perhaps a little less, a globe the visible disc of which is about 880,000 miles across. This wonderful globe is continually throwing forth an amount of light and heat in all directions into space. Of that light and heat we at any given moment are never receiving more than about a 2,300 millionth part: all the rest is passing into space, here and there intercepted by other planets and by other suns. But the vast mass of the light and of the heat which is being given forth from the sun is radiated into space. What becomes of it? That is a question which no one has answered, and no one can answer in the present state of our knowledge. Let us further consider that this vast globe is maintained in a state of intense incandescence. We have now to inquire whether we have any means of ascertaining what the cause of that incandescence is; and if we do not reach so far as that, have we any means of ascertaining the composition of the matter which is in this wonderfully active state?

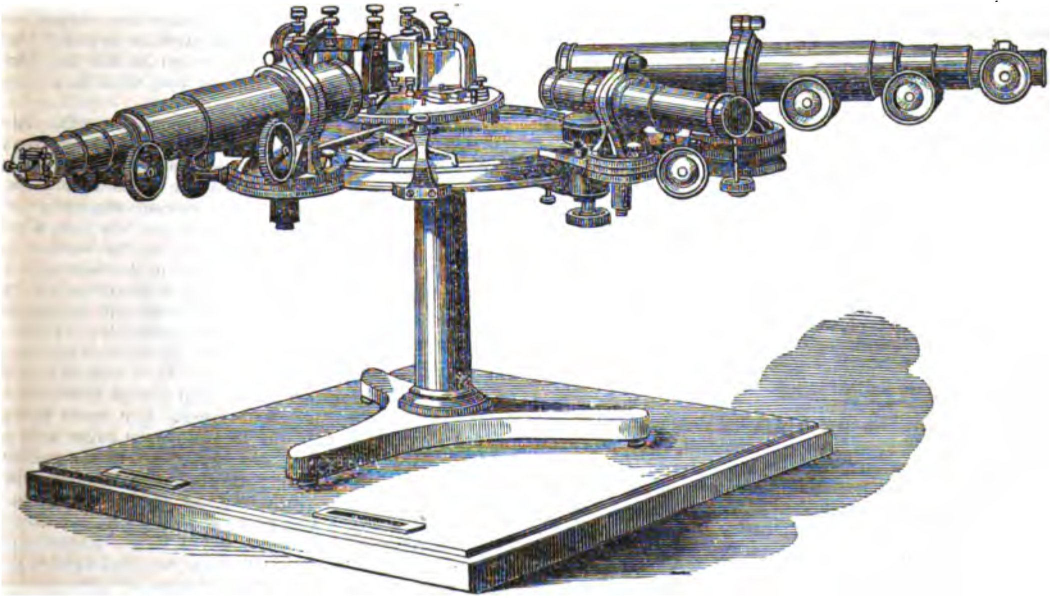
In an inquiry of this kind every aid that is at our command must be pressed into the service. The appearance of the sun, when viewed through a telescope, manifests to us the fact that the solar surface is in a perpetual state of violent agitation. It is not a smooth glowing mass of molten iron—nothing of the sort, for we can see that at different points upon the surface of the sun there are differences in the degrees of activity, and differences in the amount of light which it is giving out. The surface of the sun on the whole may be considered as made up of a series of what have been called bright granules, the forms of which have been variously described by different observers according to the powers of the instruments applied. But these bright granules, be it remembered, represent masses hundreds of miles in diameter. The distance of the sun is such that a circle, a single second of arc in diameter, which, according to Sir John Herschel, is the smallest surface we can see, is 467 miles in diameter. These masses of luminous matter are diffused over the surface of a substance which is much less luminous than itself. Upon the surface of the sun there are dark points which have been called *pores*. In addition to these appearances we have evidence, at intervals, of vast tornadoes or storms which appear to be taking place in this undulating luminous atmosphere. This luminous atmosphere of the sun, or photosphere as it is frequently called according to Sir John Herschel, is best conceived to consist of a quantity of very finely divided, highly luminous, cloudy matter in suspension in a transparent, slightly luminous body of air, differences in luminosity depending upon differences in the distribution of this suspended matter. I am very far from saying that this condition is maintained by an ordinary process of combustion. But I believe there is nothing which gives us a better notion of what the luminous particles of the sun may be, than is afforded by examining the product obtained when a substance is burned in oxygen, like phosphorus, which gives out a quantity of solid flocculent phosphoric acid, glowing with an intense white light by the heat evolved during combustion. The suspended matter in the sun is possibly liquid, but probably solid particles, which are deposited in this intensely heated, but not highly luminous atmosphere, in large cloud-like masses, these masses perpetually sinking to a lower level and as continually being raised again by currents in the solar atmosphere. In order to interpret these appearances we must call to our aid every fact that we can ascertain with regard to the physical condition of the sun. We must apply the laws of physics as we have ascertained them upon the earth. We must invent no new ones to explain these phenomena, if we would proceed in the true path of philosophical inquiry.

Supposing, then, the whole disc of the sun were filled up with matter of uniform density (a very violent supposition, I grant), it must be borne in mind that the mass of the sun, taking that portion of it which we see as its luminous disc, would be represented by a mass of matter a little less than half as heavy again as water. Again, we must remember that the effect of gravity upon the surface of the sun far exceeds its power at the surface of the earth. A pound weight upon the surface of the earth would gravitate upon the sun's surface with the force of a quarter of a hundred weight, so that at the surface of the sun the effect of gravity, like that of many forces in operation upon the earth's surface, is exaggerated to a wonderful extent.

Besides these bright granules, lying between which are the dark pores or spots producing what we may regard as the ordinary appearances, we have upon the surface of the sun, as already stated, evidence of what appears to be violent tornadoes. The luminous mass which constitutes the photosphere of the sun is from time to time apparently torn up, a thousands, aye, hundreds of thousands of square miles of i surface are tossed aside, and a vast cavity is formed in th luminous mass. I am not saying this without warrant de ed from observations upon the sun's spots, first made near a hundred years ago by Professor Wilson of Glasgow, a since confirmed in a remarkable manner by the investigatio which have been made since the state of the sun has been mo minutely examined in modern times. The most recent exa inations of this description are due to our countrymen, De l Rue and Stewart, aided by Mr. Löwy. Their investigatio show us that these vast craters in the luminous surface (if th expression may be allowed) consist of two principal portio the margin consisting of a faintly shaded portion, the *pen bra*, with a dark spot, the *umbra*, in the middle. One of th enigmas for solution is to explain what these solar spots ar Has the photosphere been heaped up to form the adjace brilliant streaks known as *faculæ*? and are these dark spo clouds of colder material which have been depressed into th photosphere, and which gradually disappear in consequen of the incandescent portions gradually again raising the clouds to their usual temperature? Are they—and I think here th evidence goes against this—are they holes in this luminous photosphere showing behind it a dark mass—the interior o the sun itself? I cannot now, however, go more minutely into the question of sun-spots, as it would be foreign to my purpose. My object is to prepare your minds by bringing before you some of the principal points in the physics of the sun, which have been ascertained from different sides by investigating the recent additions to our knowledge by the spectrum. I shall therefore simply now give you on the screen a representation of a photograph of the surface of the sun itself, which, it will be recollected, will be a reversed image of the sun; that is to say, where the sun is brightest we shall have in the photograph the greatest diminution of brightness. At the upper part of the disc you see a brilliant spot. That is a very characteristic sunspot. Remembering that the most brilliant part of the screen is that which is really the darkest on the sun, you will observe in the centre of the opening the umbra of the spot. Then around that is what is called the penumbra, or more slightly shaded portion: on the other sides are groups of spots which are in the process of formation or of healing up, for I do not know at what period this particular spot was taken. These cross lines on the photograph are merely lines of position showing which way the sun is moving. The spots cross the disc of the sun from left to right, and as they gradually diminish it is always found that the umbra is the first portion which disappears.

I wish, in the next place, to show you another fact connected with the sun, which recent observation has enabled us to ascertain. The sun is not simply a great glowing ball, such as it looks to us, but there is something outside the sun of which we in general take no notice, and of which until some twenty or thirty years ago we were in absolute ignorance. The phenomenon to which I am going now to direct your attention is only visible on those rare occasions when the disc of the sun is obscured by the passage of the moon between us and its body. In those cases, and under suitable conditions, we have an opportunity of ascertaining that the sun is surrounded by a vast atmosphere which is not in that intensely glowing and incandescent condition which the surface that we usually see is. I have here a photograph which represents an observation made by Mr. De la Rue in July, 1860. [The photograph was introduced.] This indicates to us the appearance which is seen when the whole disc of the sun, which is visible under ordinary circumstances, is entirely eclipsed by the moon. You will notice that round the dark body of the moon we have a remarkable halo of light, and that this halo is at certain points much more brilliant than at others,—that, in point of fact, there are clouds thrown up into this atmosphere. Some of these clouds have been seen detached from each other. It is estimated that the height at which these clouds occur is in some cases at least 72,000 miles from the surface of the sun, so that around the sun there is a vast atmosphere invisible under ordinary circumstances, into which invisible atmosphere are projected what you see here, and what have been called red flames, clouds, probably, of incandescent matter. In this photograph the solar atmosphere is all of one uniform tint, but as actually seen, its projections, instead of being white, are of a rich red colour, and possess considerable photographic power. What the nature of these flames may be is a point on which further inquiries are necessary. It is probable that next year there will be an opportunity of making observations upon them under conditions more favourable than have ever existed since attention was directed to these points, for in the month of August there will be a total eclipse of the sun, visible in the central portions of India, which will have the unusual duration of nearly five minutes. Thus, if the atmosphere is favourable, opportunity will be given to persons properly prepared for making observations upon these flames by means of the spectroscope, and thus probably of ascertaining what the constituents are.

I will now endeavour to explain how the spectroscope will act in determining the character of these flames, and how it has enabled us to ascertain what some of the components of the sun are. We are indebted for our great stride in this direction to the observations and discoveries of Kirchhoff. Let me call your attention for a few moments to the diagram which we have here, which is intended to represent certain appearances exhibited by the solar spectrum. Suppose the light to be admitted through a vertical slit at a distance, if it be viewed after it has passed through the prism, the spectrum so obtained will be seen to be crossed by an almost countless number of dark lines. I am not sure whether these dark bands were not first observed in this very institution, but at any rate the observation was first made by one of its most distinguished members, Dr. Wollaston. The importance of this observation was certainly not anticipated at the time it was made. He merely looked at the light coming in at the chink of a door, through a prism which he held up to his eye. Some twelve years afterwards Fraünhofer examined the solar spectrum by viewing the slit, which he placed at a distance of 24 feet from him, through a very clear prism, and by means of a telescope. He then saw not merely eight or ten bands, as Dr. Wollaston had done, but he mapped and measured nearly 600 of them, and these lines have been called after him "Fraünhofer's lines." In the diagram you see a number of letters which run along the bottom. These letters were appropriated by Fraünhofer to the indication of the most important and most prominent of the lines which he observed. Fraünhofer found that the solar lines are perfectly fixed in position in different colours, and, being an optician, he applied this observation to the purpose of determining the refractive power of the glass which he used in his lenses and prisms. These lines have always been designated by the letters which Fraünhofer gave them. Many persons have since carefully examined the solar spectrum, and some have described and mapped additional lines. Though I cannot here go into the history of this matter, I may mention particularly the names of Angström and of our own countryman, Sir David Brewster (who has latterly worked in association with Dr. Gladstone): above all we are indebted to Kirchhoff. He used an instrument exactly similar in principle to that which I described in the last lecture, the only difference being that, instead of taking a single prism as is represented in the diagram, he made the light pass through three additional prisms. The light was thrown upon his eye by a telescope. By the kindness of Mr. Gassiot I have an opportunity of showing you what I believe to be the finest instrument of the kind which has ever been constructed. It was made by Mr. Browning, and the accuracy and the workmanship have been attested by all who have used it. In this instrument the light is allowed to fall upon a battery of nine prisms, and after passing out through the last prism it falls upon the face of the telescope, through which it is viewed by a person at the other extremity. It is clear that if we transmitted the sun's rays through such an instrument they would be opened out by the successive action of the prisms, until each line was brought out in such a way that the character of that line could be ascertained with the greatest nicety. Kirchhoff carefully mapped all these lines between A and G. They vary greatly in their strength and degree of definition. This is a curious, and at the same time an important point, and as will be seen it may be made use of in order to enable us to ascertain the origin of the lines in certain cases. As I cannot project the lines of the solar spectrum itself upon the screen, I will substitute for it a photograph of Kirchhoff's map. It is a beautiful map, but there is considerable difficulty in rendering such fine lines visible to a large audience. [The representation of the map was produced on the screen.] You see how very greatly the lines vary in thickness, in blackness, and in definition. Some of them are as sharp as



a line can be drawn, while others are broad and confused and somewhat indefinite in their outlines. Hence it is evident that these lines possess a sort of character by which they can be recognised when they are again rendered visible.

[The attention of the audience was then directed to the character of certain groups of lines, particularly in the vicinity of the lines D and C.]

Before I quit this part of the subject I shall call your attention to a beautiful photograph which indicates the exact position of these lines, as produced by the action of the sun's rays upon a collodion plate. They were taken in New York by Mr. Rutherford, from whom I received the specimen before you. When compared with Kirchhoff's maps, it is wonderful to see how perfect is the correspondence, and how faithfully those maps represent the actual lines.

I once more project the map upon the screen, for the purpose of calling your attention to the green portion. There are three lines in the green due to magnesium. Underneath this map you will see a number of letters. For example, here are the letters Fe. That is a contraction for the Latin *ferrum* (iron), and it shows that every one of these lines so marked corresponds with a bright line in the spectrum of iron. There are a number of other bodies indicated in the same way; thus, Ni signifies nickel; Ca, calcium; Cd, cadmium; Au, gold. Not that every one of these metals has corresponding lines in the solar spectrum, but Kirchhoff has examined the bright lines produced by these different bodies, and has marked the position of the solar spectrum to which these lines correspond.

I will show you now the blue portion of the spectrum which is beyond the parts at which we have just looked. This black line is Fraünhofer's line G. You see what dark groups of lines there are in this part of the spectrum. Each of these lines has its own meaning, if we can only succeed in determining it, though in many cases this has not been done.

I have now to explain to you how Kirchhoff has made these lines interpreters of the composition of the sun. When a series of electric sparks is made to pass between wires composed of any metal, the spark, when examined by the prism, exhibits the special spectrum of the metal. For instance, in this case we have two wires consisting of silver. If I cause this secondary current from an induction coil to pass in sparks through the interval of air between the two silver wires, particles of the metal will be detached in a gaseous condition, and they will give the special spectrum of silver. The heat produced in this way is most intense. Any other metal may be substituted for the silver, and may thus be made to yield its spectrum, the metallic points being placed in such a position that the light of the spark shall be reflected into the spectroscope, and so into the eye of the observer.

I have already stated that it had been ascertained by Fraünhofer and other observers that a particular double black line, called D, in the sun's light, coincided with a bright line which was observed in certain flames, now known to be due to sodium. Kirchhoff, in order to ascertain the exact coincidence of the line D with the sodium lines, placed the light of the sodium so that the sun's light passed through it, and he found that, instead of getting the bright sodium line, he got a still more intensely dark line; he, in fact, discovered that the sodium line was reversed by the action of the more brilliant light of the sun, as already explained. But having found this in the case of sodium, he immediately began to examine other bodies in the same way, and he found that the lines of barium, strontium, and other metals were similarly reversed. He then began systematically to compare the bright spectra of the metals with the dark lines of the solar spectrum. When, for instance, iron is acted upon by the electric spark in the way I have described, it gives rise to a spectrum which contains some 70 bright lines in the space between the extreme red and the extreme violet. These bright lines differ very much in degrees of brightness: some are strong; some are weak; but the interesting point observed by Kirchhoff was not merely that for every bright line in the spectrum of iron there was a corresponding black line in the solar spectrum, but that they also corresponded in intensity. The brightest lines of the iron spectrum were the blackest in the sun's spectrum, and the feeblest in the iron spectrum were precisely the feeblest in that of the sun. This was a case not of the coincidence of two lines merely, which some persons might suppose to be an accident, but it was the coincidence of some 70 lines, line for line and strength for strength. It is impossible to have more striking proof of the identity of the cause by which these two effects were produced. Well, having ascertained in the case of iron that this coincidence occurred, he proceeded to take other metals, and among them magnesium. This metal gives a very limited spectrum, consisting of a remarkable triple group in the green, and that group is found to coincide absolutely in strength and in position with the dark line marked *b* in the spectrum; for when this solar line is examined with care it is found to consist of three black lines, exactly corresponding in character with the three lines of magnesium. Magnesium in vapour, therefore, is one of the constituents of the atmosphere of the sun. So I might go on particularising the character of each metallic spectrum, but to save time I have enumerated in this list all the metals which are known to exist in the sun's atmosphere:—

Sodium.
Calcium.
Barium.
Magnesium.
Iron.
Chromium.
Nickel.
Zinc.
Strontium.
Cadmium.
Cobalt.
Hydrogen.

Copper might have been added, though its presence is rather doubtful. Others are also marked as doubtful. Though many of their lines correspond with dark solar lines, yet there are other lines produced by these metals which have no corresponding lines in the solar spectrum. That may arise from the circumstance that the proportion in which they occur in the sun's atmosphere is small. As a rule, the metals which are enumerated in the list furnish bright lines corresponding, line for line, with dark lines in the spectrum of the sun.

Now, this leads me to another important point. It will naturally be suggested to the mind, "it is very true that these are lines produced in the light which leaves the sun, before it gets to us; but how do we know that they are produced in the sun itself? All the substances of which we have seen lines in the solar spectrum are bodies which we know upon the earth. Is it not possible that all these bodies may exist in such quantities in the earth's atmosphere that they may be the means of shutting out these rays of light which are found to be deficient in the sun's rays when they reach us?" That is, certainly, an important question; but it can be answered perfectly. If we had only the light of the sun to judge from, it might be a difficult point to decide; but we have in the stars a multitude of other bodies from which we derive light quite independent of that of the sun. If we found that every star gave us the same spectrum as the sun, then we might well question whether these lines were really due to matters existing in the sun, or whether they were not due to bodies in the earth's atmosphere. But, as we shall see in the next lecture, every star gives a spectrum of *its own*. Now the light which comes from the stars ought to be acted upon exactly in the same way as the light of the sun, if the cause of the lines were in the atmosphere of the earth. We find it is not so. The cause, therefore, does not reside in the atmosphere of the earth—at least in the majority of cases: although, as I shall show you presently, there are certain lines truly due to the action of the earth's atmosphere.

Spectrum analysis cannot tell us whether the visible surface of the sun is solid or liquid, or whether it is made up of cloud; because either a cloud, or a liquid, or a solid body would give us a continuous spectrum. If we took the light emitted by phosphoric acid, produced in burning phosphorus in oxygen, it would give us a continuous spectrum just as the surface of the sun does. But we know that there is a great atmosphere outside the visible disc of the sun which is revealed to us temporarily during a total eclipse. That great atmosphere contains bodies of all sorts in a state of vapour, volatilised by the enormous heat which is produced in the sun itself. Of course the farther this extends from the sun the colder it must be, and therefore there must be a point in the sun's atmosphere in which we are precisely in the position required to give this reversal of the bright lines due to each metallic vapour; that is to say, we must have an intensely heated nucleus behind a colder atmosphere; but even this colder atmosphere may be so intensely heated as to keep all these bodies, which we cannot even volatilise in our furnaces, in a state of vapour: if so, they must give us the dark lines observed in the solar spectrum, by absorbing, from the light of the incandescent nucleus of the sun, vibrations of the particular frequency corresponding with those produced by the metallic vapours themselves. Thus, in the light which comes to us, we have proof from the absent vibrations. We have, I say, a proof of the existence of these atmospheric bodies in the sun which arrest the corresponding vibrations produced behind them. That is the proof which Kirchhoff has given us of the presence of these bodies in the sun.

I stated just now that there are lines produced by the earth's atmosphere. This is a curious observation. It was first made by Sir David Brewster, and he arrived at the fact in this way. Here is a diagram, which may help to make it plain. Suppose this part to represent the globe of the earth, and here is an exaggerated representation of the atmosphere. You can see easily that if the sun were nearly vertical, the light would traverse a much smaller portion of the atmosphere than it would when its beams are nearly horizontal, near sunrise or sunset. The sun's light would then have to traverse a portion of the atmosphere nearer the earth, and greater in density than that through which the light would pass when the sun was high up; so that if the spectra are different when the sun is in these two different positions, we might then say that it is probable that this effect is due to something in the atmosphere of the earth itself. Sometimes opportunities of proving this occur accidentally. I have had myself such an opportunity. I was one day looking at the spectrum when a thunder-shower came on; suddenly there started into view a group of new lines, evidently produced by some sudden change in the air at the moment. The storm shortly after subsided, and the changes which had occurred in the spectrum vanished. M. Janssen, a distinguished French experimentalist, and Prof. Cooke, an American man of science, have both made observations which show that variations in the amount of moisture in the air are connected with changes of this kind. The experiments which M. Janssen made were of this kind. On the border of the lake of Geneva, he caused a pile of wood to be lighted on the top of a mountain. Having stationed himself on the other side of the lake, about thirteen miles off, he viewed this fire through a spectroscope, across the body of moist air resting upon the lake, taking care to have it at the same time observed near at hand, where a continuous spectrum only was seen. In this way he detected the presence of certain lines in the less refrangible end, occasioned by moisture contained in the atmosphere. He afterwards performed another ingenious experiment, which I regret that I cannot show in this theatre. He took an iron tube, of about 37 metres, that is, about 40 yards, in length, closed by plates of glass at the extremities. At one end he placed a gas flame, and then looked through the tube at the spectrum of the flame, by means of a spectroscope, and thus obtained a continuous spectrum. He then injected into the tube some steam, at a pressure of 7 or 8 atmospheres, so that he got a dense body of aqueous vapor. Then, on looking through the tube at the flame by means of the spectroscope, he saw in the red part of the spectrum, lines, something like those which are seen in the diagram,—strong bands of lines, evidently produced by the absorptive action of the aqueous vapour in the tube. The temperature and the pressure of the vapour were high, but they had nothing to do with the production of the lines; they were merely used as a means of getting a large mass of vapour into a small space.

In the application of this observation we have a number of curious and very interesting facts. You will remember that the solar light has this remarkable feature,—and, indeed, all lights are the same in that respect,—that whether it is seen directly, or whether it is reflected from a clean white surface, it still betrays its origin; that is to say, it always shows the same lines. If we were to look at the spectrum obtained from the sun's light direct, and then look at the spectrum of the same light after reflection from the surface of a cloud or from a mirror, we should find that the position and number of the lines were just the same in both instances. In the reflected light we should not have so intense a spectrum, but the lines would be in just the same places as in the direct light, and we should know for certain that the light in either case came from the surface of the sun.

Now what is true in this case appears to be true in all cases of reflection. It is true, for instance, in the case of reflection from the moon. I will throw upon the screen a representation of the moon, as it appears from one of Mr. De la Rue's recent photographs of the moon. What I want to call your attention to is this, that we have in the spectroscope the means of travelling over the surface of the moon, and examining the quality of light reflected from its different parts. Now, what use can we make of this? Suppose we wish to examine whether the moon has an atmosphere. We find, by the telescope, that we can see right down to the surface of the moon. The parts of its face are never obscured by clouds or by dark vapours connected with the moon itself. But it might yet happen that a delicate atmosphere, containing a very small quantity of vapour, existed round the moon, and the thickness of this stratum would necessarily vary when viewed at different parts of the surface. If we looked at the edge of the moon, the effect would be similar to that produced by viewing the sun near the horizon, the light which was transmitted from the edge would come through a long column of this atmosphere before it reached us. If we looked direct at the centre, of the disc, where the light would have to traverse a smaller depth of atmosphere than at any other point, we ought, if there were any atmosphere containing absorbent vapours, to observe a difference between that light and the light at the moon's edge. Now, on looking at these different portions of the moon, we find that the light comes from all parts, without any change. Hence we must conclude that if there is an atmosphere around the moon, it must be so excessively dilute that it cannot produce any absorptive change in the light which is perceptible in its spectrum.

Again: we can apply these observations to show that the moon does not shine of its own light, though we do not need the proof of that fact from this source; and we may also apply the same proof to all the planetary bodies. But though we already know that the moon and the planets shine by reflected light, in other instances the knowledge we can thus derive may be of importance to us. Take, for example, the case of a comet; does that shine by direct or reflected light? I will show you how this question may be answered. But, before doing so, it will be desirable to consider the result obtained by observations upon Jupiter,—a body which certainly shines by reflected light. And here we acquire some information regarding the atmosphere which surrounds Jupiter, because the light reflected from Jupiter is not identical with the light which falls upon it. Here is a diagram of some observations made at Tulse Hill, by Mr. Huggins and myself, which may make this clear. The spectrum of Jupiter's light shows us, in particular, a dark band in the orange. Besides the ordinary solar lines, which are very well seen in the case of Jupiter's light, there are groups of lines connected with the atmosphere of the planet. The object was to see whether the spectrum produced by Jupiter was different from that of the earth's atmosphere; and this object was attained by comparing the light of the planet with that of the sky, which was at that time reflecting the light of the setting sun, under circumstances in which a reflected spectrum from the surface of the sky itself was not too intense for comparison with the spectrum of Jupiter. These are some photographs of drawings of the appearance of Jupiter, made some years ago by Mr. Huggins, from telescopic observations. Astronomers have long believed that an atmosphere of considerable density exists around this planet. These bands or belts are produced, it is supposed, in consequence of clouds accumulating near its equator. They show us that, in all probability, the atmosphere of Jupiter is largely charged with aqueous vapor, and that the surface of the planet itself is not actually seen. Consequently, the light which we see reflected by the planet does not come from the body of Jupiter itself; it penetrates to a certain depth, and then comes back, after traversing a portion of its atmosphere; and therefore we do not know what is the actual condition of its surface. In Saturn and Mars we also obtain, by means of the spectrum, a certain amount of knowledge of the state of things upon both those planets. In the spectrum of Mars a number of bands in the blue make their appearance. It has been supposed that the red colour of Mars was produced by a peculiar colour of the soil. These spectrum observations seem to show that it is due rather to something in the atmosphere, and not to anything in the soil; because, if it were the latter, we should merely have a blotting out of the spectrum, and there would not be a series of regular bands, which have been observed in the case of Mars.

I have stated that by the method of spectrum observation we may ascertain whether comets are self-luminous, and may even attain to some knowledge of their composition. Our knowledge of the spectra of comets is, indeed, excessively limited. Donati, in 1864, made some observations; but the results he obtained were not very definite. I believe that those of Mr. Huggins, upon the small telescopic comet of 1866, are the best at present existing. It had a bright central nucleus, and around that was a nebulous atmosphere, not prolonged into a tail, as is usual in most comets. By means which I must explain in the next lecture, the spectroscope was brought to bear upon it, when it was found that the coma, or tail, gave a prolonged continuous spectrum, and in the middle of that spectrum there was a spot of bright greenish blue colour, indicating the position of the nucleus. What information does this give? It appears to show that the spectrum of the coma is produced by reflected light, and that the tail of the comet is somewhat in the position of a fog; that that fog reflects from the sun light of all colours, whilst the central portion is giving out light of its own, and light of one colour only. However, I have not time to-day to go into that point. I shall take it up again in connection with those remarkable bodies, the nebulæ, with which I shall deal in the next lecture.

LECTURE IV.

Spectra of the Fixed Stars.—Mode of Observation.—Double Stars.—Variable Stars.—Temporary Bright Star in Corona.—Nebulæ.—Clusters.—General Conclusions.

In the last lecture I gave you some account of the solar spectrum, and stated some of the principal facts which were revealed to us by its examination. You will remember that in the solar spectrum there are a great number of lines produced, as we now know, by absorptive action in an atmosphere which surrounds the more intensely luminous portion of the sun. We have learned to interpret many of these lines, and we have found that in a great number of cases they are produced by the presence of elementary bodies, known to us upon the earth, which, in the gaseous state, exert an absorptive action upon certain parts of the sun's rays. We have learned, also, that there are certain bodies which are not present in the sun—among them gold, silver, lithium, and several others. But there are still a great number of lines of the nature of which we know nothing. Many, no doubt, will be explained as we proceed further with our investigations into the spectra of terrestrial elementary bodies. Notwithstanding the efforts that have been made within the last few years, our knowledge of terrestrial spectra can be at present considered to be only in its infancy. We can not know what elements, indeed, are still existent upon the earth. We can not be supposed to have come to the end of our knowledge upon this point, for within the last five years no fewer than four of these elementary substances have been discovered by the simple application of this method of spectrum analysis.

The investigation of the solar spectrum, difficult as it is, is one considerably favoured by certain circumstances. We are not limited by season, or the angular altitude of the sun, but can pursue the investigation whenever the sun shines. Moreover, we can command any amount of light which the eye can bear. We can, therefore, by the action of an almost unlimited series of prisms, dissect and open out that solar spectrum, and so scrutinise, with minute accuracy, the position and character of every line which it contains.

I have to-day to refer to other sources of light which may be analysed in a similar way, but the study of which presents difficulties of no ordinary character. I propose to explain some of the methods which have been adopted for the examination of stellar spectra, and to state the chief results obtained by that examination, and I shall conclude by giving you some account of the remarkable and unexpected results obtained by a study of some other still fainter objects which are visible in the heavens—the nebulæ.

It may be necessary for me to give you some notion of the kind of difficulties with which we have to contend in these enquiries, in order to explain how it is that the results, important as they are, are still very imperfect. Solar light, as I have said, may be obtained in unlimited quantity; but when we examine the spectra of the stars we have to deal with points of light. We must collect the light, therefore, and for that purpose either a large reflector or refractor is necessary. Cumbrous machinery is required for moving the tube to enable it to follow the motions of the star, which is apparently perpetually shifting its place in the heavens. We have to bring this light to a point by means of our lenses. The more accurate our telescopes the more exactly is this light brought to a mathematical point. Now, if we attempt to analyse by means of a prism a point of light like this, we shall spread it out into a line, but that line will be so exceedingly narrow that we shall not be able to trace across it the lines of which we are in search, and which are to speak to us of its nature. The first thing, therefore, we have to do, after we have obtained our point of light, is to open it out into a line. That may be done, as was practised by Fraünhofer, by means of what is known as a *cylindrical* lens. I shall endeavour to throw upon the screen a little point of light, which you may, if you please, for a moment consider to be a star, and will then elongate its image into a line of light.

[A circular spot of light was projected upon the screen, and then by means of a cylindrical lens expanded into a line of light.]

Though I can imitate a star in the exceeding minuteness of its light, I, unfortunately, cannot imitate it in the quality of its light, and, therefore, on this occasion, I shall not be able to show you the spectra themselves, but I shall have recourse to photographs from careful drawings made upon the observations of the stellar spectra. In the observations from which these drawings were made an achromatic object glass of eight inches aperture was used, and the observations were made at the observatory of Mr. Huggins, at Tulse Hill, where he and I worked together for some years upon stellar and planetary spectra, and where he has since still further added to our knowledge by his examination of the nebulæ.

Having obtained our line of light, the next thing is to project it upon a suitable instrument for making the observations, and this line of light must be kept absolutely steady at the end of a tube ten feet long, upon a slit, the width of which is not more than the 300th part of an inch, or much finer than any ordinary hair. Obviously, this can be obtained only by an exceedingly smooth motion maintained by the clock movement of the telescope.

Here is a star spectroscope in the form which, after many trials, we found to be most convenient for these observations. I am indebted to the kindness of Messrs Simms for the loan of this beautiful instrument, which they are going to send to Professor Cooke, in America. I am also indebted to Mr. Browning for the opportunity of showing you another instrument intended for Mr. De la Rue, which is, in some respects, even better for our purpose, because it enables us to see the parts of which it is composed. This instrument of Messrs. Simms is provided with shutters, so as to exclude dust and other sources of injury to the prisms within. When in use the spectroscope is attached to the eye-end of the telescope, instead of the ordinary magnifying power, and will be carried round with it, accurately following all its motions. The cylindrical lens is placed between the object-glass and the slit, so that the light, instead of falling upon the slit as a point, shall fall upon it as a line, such as I just now showed you, only much more definite than the line which was projected upon the screen. The line of light having fallen upon that slit, is then passed through an apparatus precisely similar in principle to the spectroscope which we examined in the last lecture.

The light of the star is brought to a focus by the action of the object-glass of the telescope itself, exactly at the spot occupied by the slit of the instrument. But before reaching that spot, it passes through the cylindrical lens, by means of which it is spread out into a line, instead of a point. After passing through the slit, the light falls upon a collimating lens—that is to say, upon a lens the object of which is to bring all the rays that fall upon it into a parallel direction. The rays rendered parallel next fall upon a couple of prisms—the first prism dispersing the light to a certain extent, and the second dispersing it still farther, and producing a spectrum of the star, the most refrangible end being that which is most turned from the original direction. The spectrum then falls upon the lens of a small telescope, by means of which the image can be viewed at the proper distance. The object of the screw beneath the tube is to enable us, by a regulated movement, to carry round the small telescope, so that each part of the spectrum can be successively examined. There are cross wires in the telescope, so that, on bringing any of the lines in the star spectrum one after the other upon the cross wires by the micrometer screw, the distance between the lines may be measured exactly.

The object which we had in view in these investigations was not merely to ascertain that the lines existed in the stellar spectra, for that had been done by Fraunhofer, Donati, Secchi, and others, but to determine what these lines represented—to ascertain the constituents of the stars if possible; and that could be done, approximately at least, by measuring the position of each of these lines, and then comparing it with a map in which the lines of certain metals had been laid down, these metals having been examined by the same instrument as that which was to be applied to the stars. This, however, although it would give a result which was very valuable to us as suggesting what probability there was that certain metals were present in these stars, did not give us that absolute certainty respecting the nature of the substances which it seemed it was possible to attain by another mode of experimenting. That mode consisted in reflecting into the instrument the light produced by a series of electric sparks sent through wires of different metals in succession. In order to attain this object we have attached to this instrument a means of producing sparks between two points of silver. The instant that this circuit is included between the terminals of the secondary wire of an induction coil, a torrent of electric sparks passes between the two silver points. The light is reflected from a mirror, by which it is thrown, through an opening in the side of the tube, upon a little prism which acts as a reflector, and sends the light through the slit into the spectroscope for examination. In this way various stars can be submitted to experiment, but it is obvious that even here, although we have at command a large instrument, we are limited by the brightness of the stars. We cannot examine with any degree of precision stars which are below a certain magnitude, the quantity of light being too small. I shall endeavour to show you the results of the most accurate observations we have been enabled to make. Amongst these stars there are two in particular which are of special interest. These two are Aldebaran, the bright, reddish star in Taurus, and α Orionis, or [illegible]elgeux, the principal star in Orion. Here is a list in which are mentioned, certain elementary substances, all of which have been found to produce lines coincident with certain lines in this star Aldebaran:—

Sodium,
Iron,
Magnesium,
Hydrogen,
Calcium,
Bismuth,
Antimony,
Tellurium,
Mercury.

There is not merely the coincidence of a single line in each case, for that might be an accidental circumstance, but the principal bright lines in each spectrum produced by these bodies have corresponding black lines in the spectrum of this star. You see that there are here nine of the substances known to us upon the earth. By similar means we ascertained the absence of certain other bodies; these have no coincident lines in the star spectrum. Among these are nitrogen, tin, lead, cadmium, lithium, cobalt, and barium. We have ascertained not simply what are there, but what may not be there. Of the lines which are contained in this star we measured no fewer than seventy, notwithstanding the faintness of the object. Actual measurement, however, is possible only with a certain number of lines. There are an indefinitely greater number of lines existing in the spectrum of the star, many of which might possibly be measured by the devotion of still more time and application.

These observations are excessively fatiguing to the eye, and require special conditions of the atmosphere. A clear night, which would be very favourable to observations made simply with the telescope, might not be suitable for observations with the spectroscope. The slightest flicker or tremor in the atmosphere disturbs the accuracy of the observation. It must be remembered that we are not observing approximative coincidences, but we are desiring to observe absolute coincidences—coincidences between the bright lines of the metals we have on the earth and the black lines in the spectrum of the star.

In α Orionis we measured eighty lines, and amongst these we find that six of the metals of the earth had lines coincident with those in this star, viz.:—sodium, iron, magnesium, calcium, bismuth, and thallium (?), and that a still larger number were not coincident.

I shall project upon the screen a representation of the spectra of these two stars. They will both be visible together. The upper spectrum is that of the star in Orion, the lower one that of Aldebaran.

Beneath each diagram a number of bright lines may be seen. These represent the bright lines produced by causing sparks to pass between points of different metals attached to the coil. For example, here we have a line marked Sn. This is one of the lines indicating tin, but it has no corresponding line in the star, though we were able to measure within 5000th of an inch, or the 1800th part of the length of the entire spectrum, the coincidence between two lines. Here are the three lines of magnesium which have corresponding lines in the spectrum of this star. Here is the double line D in the sodium spectrum. That is a bright double line corresponding perfectly with two black lines in the star. Sodium is one of the most widely diffused substances in the stars; magnesium and iron are also present in both these stars. The lines in this photograph only extend to a certain distance into the blue. Here is the line *b*, and this is the line F, which is upon the margin between the green and blue. Note in passing that there is no line corresponding to F in the star α Orionis. There is a strong line corresponding to it in Aldebaran, but no line in the other. This line F is one of those due to hydrogen. I carry you to another—near the end of the red. Now this line in the spectrum of Aldebaran is a marked line corresponding with Fraunhofer's solar line C. That line also occurs in the spectrum of hydrogen. There are three lines in the spectrum of hydrogen—C, F, and G; but the point of int[illegible] here is that none of these lines are present in the star α [illegible]nis, and we conclude that there is no hydrogen there. Besides these are a large number of other lines, some of which are interpreted, others still await interpretation.

We are not yet able to explain in the case of these stars, any more than in that of the sum, what every line indicates. It may very well be that many of these lines are caused by substances which are known to us, but of the spectra of which we are still ignorant; in other cases it may well be that they are produced by substances which are not known to us, and which have no existence, indeed, upon our planet. Amongst the substances which are present in the atmosphere of these stars, are some which are present in our own sun. In other instances, as in the case of bismuth, metals are found in these stars which furnish lines which are not present in the atmosphere of the sun. Both in Aldebaran and in α Orionis there are lines corresponding with those of bismuth. Tellurium appears to be an important element in the absorbent atmosphere round Aldebaran. Then there are also in the atmosphere of this star substances such as antimony and mercury, which we consider to be poisons. Here is the bismuth spectrum thrown upon the screen. Though not so striking as that of some other metals, its characters are sufficiently strong to enable us to pronounce with certainty upon the presence or absence of lines corresponding with this substance in any star with which its spectrum is compared.

(To be continued.)

On the Absorption of Gases by Metals, by Dr. Odling, *F.R.S., etc.*

In a Friday evening lecture which I had the honour of delivering here before Easter, I drew your attention to a very singular property possessed by the metal platinum, some very beautiful specimens of which are exhibited in the library, through the kindness of Messrs. Johnson and Matthey, to whom I am also indebted for the greater portion of the articles upon the table. Now platinum, especially that which has been solidified after fusion, appears, at any rate, to be a perfectly homogeneous metal. It does not show the slightest evidence of porosity, and is absolutely impermeable to the passage of gas through it. For instance, if we take a wide platinum tube, drawn out from a single piece of fused platinum, and seal one end by soldering on to it a piece of platinum foil, and similarly close the other end with another piece of foil having a small central orifice, through which a narrow attachment tube projects, we shall have a hollow cylinder of platinum, from which, by connection with the barrel of an ordinary air-pump, or with an air-pump of Sprengel's construction, the air can be exhausted as readily and completely as from a glass tube. That is to say, as perfect a vacuum can be produced and sustained within a tube of platinum as within a tube of glass. Not a particle of air passes bodily from the external atmosphere through the substance of the metal into the internal vacuous space by means of atmospheric pressure, and, what is more to the purpose, not a particle of air passes molecularly through the metal by means of the far more refined and accusing process of diffusion; and this is true, not only of atmospheric air, but of every gas with which the experiment has been made, and is doubtless true of all gases whatsoever. But if, instead of making such an experiment with the platinum tube at ordinary temperature, we make it with the tube at a red heat, under this condition the metal still remains perfectly impervious to the passage of atmospheric air, and of all other gases—except one. One gas alone, under those circumstances, is found to penetrate the platinum, even with very considerable facility, and that gas is hydrogen. The fact that hydrogen has this distinctive property of penetrating ignited platinum, first observed by M. Deville, of Paris, evidently shows that there is something peculiar, something altogether special, in the relation subsisting between the gas and the metal, to which the effect is due. The mode in which the experiment has been recently made is of this kind:—The platinum tube is first attached to an air-pump of Dr. Sprengel's construction, which acts on the principle of the trompe. We have mercury constantly dropping from a constricted funnel down a long narrow glass tube; and as each drop of falling mercury is sufficient to fill the tube, each such drop acts as a small piston which pushes down a column of air before it, and by pushing down successive portions of air eventually effects a complete exhaustion of any vessel communicating with the fall tube. Indeed, by an instrument of this kind, as perfect a vacuum can be obtained as in the Torricellian vacuum itself, and by its employment a vacuum is easily obtained in the interior of our platinum tube. Before being exhausted, the platinum tube is placed within a tube of porcelain; while in the space between the two tubes a current of hydrogen is continually passed. The internal platinum tube being rendered vacuous, the external porcelain tube is heated in any form of furnace,—in a gas furnace, for instance, as shown here, or in a charcoal furnace; and so soon as the external porcelain tube acquires a bright red heat,—so soon in fact, as the interior platinum tube becomes red hot,—and not till then, do we find that as each drop of mercury falls through the tube of the pump, it carries before it a certain quantity of air or gas which it delivers into this small inverted test-tube of mercury placed for its reception. So soon, therefore, as the platinum tube becomes red hot, a portion of the hydrogen gas confined in the intermediate annular space between the porcelain and the platinum tubes, enters the platinum tube, is exhausted from its interior by means of the Sprengel pump, and is delivered into the test-tube for examination.

There is another metal, namely palladium, one of the platinum group of metals, and closely related to platinum, through which the transmission of hydrogen is yet more easily exhibited, since a temperature very far short of redness is sufficient to render this metal pervious to the gas.

Here is an ordinary apparatus for generating hydrogen. The gas passes through sulphuric acid to dry it, and then through the glass tube in which the palladium tube is contained. You see it from time to time take fire, though it does not burn continuously in consequence of its being delivered through the sulphuric acid in the form of bubbles. The small tube of palladium, contained within the glass tube, is made exactly like our platinum tube, except that it is much shorter. At the present time it is vacuous, having been exhausted by means of the Sprengel pump before the lecture. If you will direct your attention to the small inverted test tube of mercury, you will see that at the present time there is no gas being delivered into it, but we will now heat the palladium tube gently through the glass tube, and long before it gets to a red heat you will find that some of the hydrogen gas which is passing outside the vacuous palladium tube will penetrate through the thickness of the metal into the interior of the tube, be sucked from its interior by means of the Sprengel pump, and delivered into the test tube. I have no doubt that after a few moments, you will see that a quantity of gas will be delivered into the test tube in this way, which gas we shall see to be hydrogen, sucked from the interior of the tube of palladium, through the substance of which it has been transmitted. At the present moment, if you listen, you will hear each drop of mercury falling just as it falls in a barometer; but in a few minutes—and I must beg your patience for this experiment, because it will take some little time—we shall lose this clicking sound, through the entrance of gas into the full tube; of which gas, after a little while, we shall get an appreciable volume delivered. A few bubbles of gas have already come over. Those who are near can see that a quantity of gas is being gradually collected in the inverted test tube, which will soon amount to several cubic centimètres. On now putting a light to it, you see that it takes fire and burns in the characteristic manner of hydrogen. Within a few minutes, then, hydrogen, to the amount of several cubic centimètres, has passed from the exterior of the moderately heated palladium tube, through the substance of the tube, into its previously vacuous interior, whence it has been sucked out and delivered by the Sprengel pump.

A curious point of interest is that, in the case of heated palladium, as in the case of ignited platinum, hydrogen is the only gas which passes through the metal. If we take a mixture of hydrogen gas with some other gas, the hydrogen only is sucked through the platinum or palladium, the other gases remaining untransmitted. From the complex mixture of gases, for instance, which constitute ordinary coal gas, hydrogen may be separated in a perfectly pure state by its passage through heated platinum or palladium, which are impervious to all the other coal-gas constituents, as I had the honour of showing you in my former lecture.

Now what is the nature of this transmission of hydrogen through solid metal? On the last occasion, I had an opportunity of demonstrating to you that the phenomenon had no relation to those physical actions which are denominated transpiration and diffusion, but that it was an action of an entirely peculiar character, and was probably preceded by an absorption of the hydrogen in the substance of the metal; and this absorption of hydrogen by platinum, and of other gases by other metals, forms the subject of my present lecture. I wish to show you that in these cases the passage or transmission of the hydrogen gas, through the platinum or the palladium, is preceded by an absorption of the hydrogen gas in the substance of the platinum or the palladium.

The experiment is made in this way: in the first instance some platinum wire is introduced into a porcelain tube of this description, which is closed at one end, and at the other end connected with a Sprengel-pump. The tube is then heated, and its interior rendered vacuous. After the establishment of a vacuum, hydrogen gas is passed over the red hot platinum wire contained in the tube, and the platinum gradually and slowly allowed to cool with the hydrogen gas still passing over it, so that if the platinum has any power of absorbing hydrogen gas it shall have every chance of doing so, and shall, so to speak, select its own absorbing temperature, from the temperature of a red heat down to that of the atmosphere. The platinum was then removed and exposed freely to the air, so that any accidental hydrogen adhering to the surface might be removed. It was then introduced into another tube of this kind, which in this particular case is made of glass in order that it may be seen through, but which, in the actual experiment, was made of porcelain. This tube, containing the charged platinum wire, was attached to the Sprengel pump, and again perfectly exhausted,—the air removed from it by the exhauster being found absolutely free from hydrogen. Then heat was applied, and, at the moment when the tube became red hot a delivery of hydrogen gas began to take place, and continued for some time, showing that the platinum had absorbed a certain quantity of hydrogen gas, which it delivered up at a red heat under the influence of the vacuum. In the first experiment, then, from fused platinum exposed in this manner to the action of hydrogen at a red heat and gradually decreasing temperature, there was afterwards extracted as much as 21 per cent. of hydrogen.

Now what was the nature of this behaviour of platinum towards hydrogen? Did it depend upon surface action? If so it would be increased by an increase of the surface of the platinum. The wire was accordingly drawn out to four times its length, which would give rather less than four times the former surface; but in this case only 17 per cent. of hydrogen was extracted after treating the wire as in the previous experiment. Quadrupling the surface, therefore, did not increase the quantity of gas absorbed, and it was found on a repetition of these experiments that the quantity of gas absorbed gradually got less and less. In a third experiment with the same wire, the quantity absorbed amounted to only 13 per cent.

Now comes the question, if this power of the metal to absorb hydrogen is not a question of surface, is it a question of texture? Accordingly, spongy platinum was employed, and in that case it was found that the metal absorbed 148 per cent. of gas, that is, about 1½ times its volume of hydrogen gas, measured at the temperature of the atmosphere. As fused platinum we had the metal in its densest, or rather in its most compact form. As platinum sponge we had it in its most porous form; while as ordinary wrought platinum we have it in a sort of intermediate form—not so porous as the one, and not so compact as the other. What, then, was the result obtained with the wrought platinum? Well, it was found that one volume of wrought platinum absorbed 4·8 times its volume of hydrogen, or 480 per cent. This is the mean of three experiments made with the same portion of platinum. One of them gave 5·5; another gave about 4·9; and the other gave 3·8 volumes of gas. The next experiment was made with a different portion of platinum; and in this case, although the metal contained 3¾ times its volume of hydrogen gas (379 per cent.), measured cold, it was found that none of this gas could be evolved into a vacuum except at a red heat. At first the platinum was submitted to a temperature of 240°, but not a particle of gas was given off. The metal was then heated by a small Bunsen burner to a temperature just short of redness for an hour, and still no gas was given off; not, indeed, until the temperature arrived at the point of redness, could any gas whatever be extracted.

We are all of us familiar with the effects of atmospheric pressure, and know that a variety of experiments have been devised by which the results of this pressure may be manifested. One of these is the common experiment of bursting a bladder stretched over a short glass cylinder exhausted by the air-pump. [This experiment was performed, a sharp report accompanying the breaking of the membrane.] Now, let us compare the force exerted by atmospheric pressure in this way, with the force exerted by platinum in condensing hydrogen gas. Let us consider the experiments of which the mean result was 4·8. As I have said, one of these experiments gave 5·5; and for the sake of taking round numbers, we will say that 5 volumes of gas were absorbed by one volume of platinum. Taking a cubic centimètre of platinum, then, it absorbs five times its bulk of gas. To condense these 5 centimètres of gas into the space of one cubic centimètre, would require the pressure of five atmospheres; or five times the force just exerted by the air in bursting that bladder. But at the temperature at which the experiment was made, these five centimètres were really 15; and accordingly, we have to consider the compression of 15 cubic centimètres of hydrogen into one cubic centimètre, for which purpose we should require 15 times the atmospheric pressure which was just employed. But in reality, this does not represent anything like what has been done. We have not merely compressed these 15 volumes of gas into 1 cubic centimètre of space, but we have compressed them into so much of 1 cubic centimètre of space as appears to be fully occupied by platinum, but is not really so occupied. If we assume, for instance, that in this cubic centimètre, which appears to be all platinum, there is, say, one thousandth part of it which is not platinum, to compress our 15 cubic centimètres of hydrogen into this space would require a pressure of 15,000 atmospheres. So that when this piece of platinum absorbs 15 times its bulk of hydrogen gas at a red heat, it exerts some 15,000 times the compressing force that was exerted by the atmosphere in bursting that bladder.

My time is passing away so rapidly that I fear I shall have to omit a good many points of interest; but I may direct your attention to the fact that, although the evolution of hydrogen by platinum takes place only at a red heat,—and indeed some charged platinum that had been preserved for two months was found still to retain the whole of its hydrogen—yet the absorption of the gas by the metal takes place at a much lower temperature. Thus at 230°, platinum absorbed 1½ times its volume, or 145 per cent., and even at a temperature below 100°, the boiling point of water, it absorbed 76 per cent. of gas.

When, however, we come to speak of palladium, the facts are far more striking even than with platinum,—palladium appearing to be a metal altogether special in its relations to hydrogen, which it absorbs abundantly even at a comparatively low temperature. A piece of wrought palladium foil heated to 245° was found to absorb 526 times its volume of hydrogen, the gas being measured at the ordinary temperature; but it was found that even the temperature of 245° exceeded the most suitable point, and that at the temperature of 100° the metal absorbed 643 times its volume of the gas. Now, if it is a difficult thing to conceive how 15 cubic centimètres of hydrogen should be compressed into the interspace existing in a cubic centimètre of platinum, still more difficult is it to conceive how 6 mètres of centimètres of hydrogen should in the same way be compressed, not into one cubic centimètre of space, but into so much of what seems to be a cubic centimètre of palladium as is not really occupied by the palladium. At a temperature falling short of 20°, that is without the limits of ordinary atmospheric temperature, the palladium still absorbed 376 volumes of gas.

In the case of spongy palladium, of which I have here a specimen, there was not such a difference between it and the wrought palladium, as there was between the spongy platinum and the wrought platinum. It was found that the spongy palladium absorbed 680 times its volume of gas, while the wrought palladium absorbed 643 times.

Here is some wrought palladium foil which has been charged in the manner I have described, and now contains some six or seven hundred times its volume of hydrogen locked up or occluded in it. This hydrogen does not come off appreciably, or only in very small proportions, until the metal is heated, but on the application of heat, we shall be able to collect the gas with facility. The piece of foil has been charged with hydrogen gas at a temperature of 200°, then exposed freely to the air, and afterwards introduced into the tube. The tube is then exhausted, and now we are beginning to heat it. On the application of heat, the hydrogen gas will be given off and delivered in the test tube as in the former experiment, the only difference being that in the former experiment, we sucked the hydrogen through the tube, and in this case we are extracting the hydrogen which has been absorbed by the metal. It will take some little time for us to collect any considerable quantity, but you see already that the hydrogen gas which was absorbed by the palladium, is now being given off by it. Mr. Roberts, to whose zeal Mr. Graham and myself are both much indebted, has now got the hydrogen in the test tube, and on my applying a light, you perceive the combustion of the hydrogen gas, which we have just extracted from the charged palladium.

The hydrogen gas condensed in this way in the substance of the palladium is capable of exerting certain chemical actions which hydrogen gas in its ordinary state is not. We find that this condensed hydrogen acts as nascent hydrogen, exhibiting all those reducing actions which are characteristic of nascent hydrogen. To give you an illustration of some of these chemical actions of the condensed hydrogen, we have here a solution of permanganate of potassium, into which we will introduce a portion of the palladium charged with hydrogen. The action will not be immediate, but after a little while you will see that the permanganate will become decolorised by the action of the hydrogen which has been absorbed into the palladium. Here we have some solution of the ferricyanide of iron, and on putting into it a portion of the charged palladium, we shall have a gradual development of Prussian blue. The difficulty of the experiment is that the palladium, being heavy, sinks, and does not come much into contact with the liquid; but even now you see that a certain amount of blue tinge has been imparted. You also see that in the other vessel which contains the permanganate a certain amount of bleaching action has taken place. Hydrogen, in this form, will also bleach the iodide of starch. If we introduce into that compound some of this hydrogenetted palladium, hydriodic acid will be formed, and the blue colour of the iodide of starch disappear, though the action will require some little time. In the case of the ferricyanide of iron solution a very decided blueing has now taken place, which will increase to a yet more obvious extent. The permanganate is already almost bleached by the reducing action of the hydrogen absorbed into the palladium, while the colour of the iodide of starch is gradually disappearing. By these results you see that hydrogen is capable, when thus absorbed, of producing those characteristic chemical effects which, under ordinary circumstances, are only observed of so-called "nascent hydrogen."

There are a great number of other interesting points connected with the absorption of gases by these two metals, palladium and platinum; but my time is getting on so rapidly that I must proceed if you please to consider the absorptions manifested by some other metals. In the case of copper it is found that this metal, in the form of wire, will absorb 30 per cent. of hydrogen, whereas in the spongy form it will absorb 60 per cent. Gold is unlike platinum in this particular—that it will absorb a great number of different gases, whereas platinum absorbs hydrogen only. Gold, in the form of assay cornettes, was found to absorb 48 per cent. of hydrogen, 29 per cent. of carbonic oxide, 16 per cent. of carbonic acid, and 20 per cent of air, but of this air, absorbed by the gold, nearly the whole was nitrogen. Whereas ordinary atmospheric air contains 21 per cent. of oxygen, the air absorbed by gold contained only 5·3 per cent. of oxygen. Gold, therefore, seems to be a metal which is singularly indifferent to oxygen. Before charging the cornettes with carbonic acid or carbonic oxide it was necessary to ascertain that they did not contain any gas in the first instance. But it was found that they really did contain a considerable proportion of what may be called natural gas, which had to be removed from them. The gas amounted to 212 per cent. The gold cornettes actually contained twice their volume of natural gas, which consisted chiefly of hydrogen and carbonic oxide, with the exact proportions of which I will not trouble you, and which had been absorbed from the muffle furnace in which the cornettes had been originally heated.

(To be continued.)

ACADEMY OF SCIENCES.

June 24, 1867.

(From our own Correspondent.)

M. Chevreul, president, read a letter from the Minister of Public Instruction announcing to the Academy that the election of M. Yvon de Villarceau in the section of Geography and Navigation was approved by an Imperial decree of the 19th June.

M Elie de Beaumont read a letter from M. Agassiz, dated last November, in which this *savant* gives details on his voyage up the river Amazon and its tributaries. He has found that that part of the American continent is formed of mud or diluvium resting on a cretaceous deposit, similar to the basin of the Seine or banks of the Somme.

M. Rouget addressed a memoir in which he differs from the opinions lately put forward on muscular contraction.

M. Thomas gave a paper on cholera remedies.

M. de Paravay, on ancient Chinese books.

M. Edward Robin, on the length of life.

M. Clausius, now in Paris, presented a copy of his work on the "Theory of Heat."

M. Velpeau sent a note by Trubart on a new mode of the introduction of medicaments. He had only made a small number of experiments, which he communicated in order to take date. For cephalalgia, ophthalmia, etc, he uses remedies introduced by the nostrils.

M. Charles Deville communicated the observations made by M. Janssen on the eruption of Santorin, and submitted the flames to spectrum analysis. The results are, the presence of sodium in abundance, carbon, chlorine, and copper. Experiments made on Stromboli gave the same results.

M. Balard presented the work of M. Friedel on silicates and other chemical products.

M. Jules Pernot, of Avignon, sent a note on the preparation of silicates and other chemical products. He has obtained a first-class material for calico-printing, etc.

M. de Pambour read a paper on hydraulic machines.

The Academy named two commissions, one for prizes for statistics and another for the Bordin prize.

M. Artur gave some explanations of his theory of the molecular actions, capillary attractions, and chemical decompositions.

M. Zalewski read a note on the method of augmenting the power of the Bunsen pile.

M. Caron criticised the artificial processes for preparing substitutes for milk, and concluded by pronouncing them indigestible and injurious to infants.

M. Daubrée read a note of M. Bonafous on the meteor seen on June 11, at 8h. 25m.

July 1, 1867.

New Volcanic Islands.—Works of Lagrange.—Sir D. Brewster on Lighthouses.—Aniline Colours on Cotton.

M. Chevreul, president, opened the meeting, and in the absence of the perpetual secretary read the correspondence, minutes, etc.

M. C. St. Claire Deville handed in a note inserted in a Portuguese journal, the *Perseverangia*, announcing that between Tersira and Graciosa, two islands near Lisbon have been subjected to continual volcanic eruptions; very strong shocks of earthquakes have been felt, and have produced many islets, one after the other, analogous to those of Santorin in Greece. On the 1st June a submarine volcano cast up igneous matters in such quantity, that a tongue of land has been formed with the continent. This ground is as yet unapproachable, on account of the incandescence of the rocks, as well as the sulphurous vapours from the fissures. M. Deville asked that the Academy should take an interest in these new eruptions as it did in those of Santorin.

M. Treuil read a note on the lactiferous vessels of fig-trees and euphorbiacea.

M. Serrett presented to the Academy the first volume of the works of Lagrange, which were published under his direction by order of the Minister of Public Works. This great work consists of eight volumes of 1,800 pages each, with plates, and will be distributed to each member of the academy. They contain papers on mathematics, chemistry, physics, anatomy, hydraulics, etc.

Sir David Brewster sent a very interesting memoir on the history of lighthouses and dioptric apparatus.

M. Morris sent a copy of his book on wine-making, etc.

M. Fournet, of Lyons, sent a great memoir on atmospheric electricity.

M. Chevreul read a note from M. Biddeman, at Berlin, on aniline colours for cotton.

The meeting then resolved itself into a secret committee to elect a member in place of M. Pelouze, deceased. MM. Cahours, Berthelot, and Wurtz are proposed; M. Wurtz will most likely succeed to the vacant chair.

July 9, 1867.

Practical Meteorology.—Letters from Routrou *to* Cardinal Richelieu.—*Alleged Discovery of the Law of Gravitation by* Pascal, *prior to* Newton.—E. Becquerel *on Capillary Chemistry.—Researches on Benzol and its Derivatives.—Cause of Tubercular Disease.*—Daubrée *on the Classification of Meteoric Stones.—Theory of Volcanic Upheavals—Telescopic Views of the Great Nebula in Orion.—Election of* Adolphe Wurtz, F.R.S., *to the Academician's Chair, vacant by the Death of* Pelouze.

M. Chapelas-Coulvier-Gravier presented to the Academy a small volume which he published under the title of "Practical Meteorology."

M. Chasles presented to the Academy two letters from the poet Routrou to Cardinal Richelieu. In the first, Routrou advises the celebrated minister to found, in Paris, a literary society analogous to that of the floral games of Toulouse; in the second he thanks him for having seriously entertained the proposition by founding the French Academy. To these presents M. Chasles added two other letters, one from Routrou to Corneille, and another from Corneille to Routrou. M. Chevreul reminded M. Chasles that he told him one day that he (the latter) was in possession of two autograph letters, from which it resulted that Pascal had discovered and calculated, before Newton, the law of universal gravitation of masses, in the inverse ratio of the square of the distance. Pascal was born in 1623, died in 1662, and Newton only made his great discovery in 1665. If it is true that, in documents written by his hand, Pascal had established the law of gravitation, it is certain that he was in advance of Newton. The documents M. Chasles possesses are: the first, a letter written by Pascal to Robert Boyle, the illustrious physician; the other is a note certainly written by his own hand. M. Chasles promised to bring to the Academy, on Monday next, the two precious documents, and to make them the subject of a more explicit communication.

M. Becquerel, sen., read a third communication on capillary chemistry. He pointed out new facts of chemical decompositions taking place under the influence of capillarity, and he thought he has proved that these truly curious phenomena were produced under the triple influence of affinity, capillarity, and electricity. To demonstrate the intervention of electricity, M. Becquerel has made the following experiment: he immersed his *split* bell-glass, containing nitrate of copper, in a second bell containing a solution of monosulphide, as in the first experiments; then he dips the two extremities of a silver wire, one into the nitrate and the other into the monosulphide. A constant electric current is formed: 1. The deposit of silver is made not in the capillary slit, but on the iron; 2. When the wire is removed the deposit is formed in the slit and on the edges along the side of the split bell-glass. The capillary action is as powerful as an electrical action. M. Becquerel continues to improve his experiments; for the split bell-glass he substitutes prisms of crystal glass pierced with a small hole; the slit or fissure is replaced by plates of glass with edges in contact, or even by sand; and he has thus obtained effects of silvering, gilding, platinising, and very remarkable deposits of gold, silver, nickel and cobalt.

M. Zinin, of the Academy of Sciences of St. Petersburg, read a *resumé* on his researches on benzol and its derivatives, azobenzol, azoxybenzol, etc.

M. Velpeau read a letter in which M. Lebert, of Breslau, states that he thinks he has found the cause of tubercular disease in the shortening of the pulmonary artery.

M. Daubrée enumerated the bases of the classification and methodical arrangement of the collection of meteoric stones and iron of the Museum of Natural History.

M. Edmond Becquerel communicated an observation, of M.

Janssen, from which it results that the oscillatory motions of volcanic upheavings are always perpendicular to the faults that can be compared to an opening, the edges of which open and shut by turns.

Father Secchi, of Rome, handed in two telescopic views of the nebula in Orion, made in 1859 and 1865.

The Academy then formed into a committee for the discussion of the claims of the candidates for the chair in the chemical section, rendered vacant by the death of M. Pelouze. The section presented in the first place M. Wurtz, and secondly in alphabetical order, M. Berthelot, and M. Cahours. M. Wurtz, the discoverer of glycol, and compound ammonias, is most likely to be elected unanimously. The discovery of glycol and compound ammonias gained for him the prize of £400. His "Chemical Philosophy" has been translated into many languages—into English by Mr. Crookes, etc.; his claims are of the first order, even in the presence of the innumerable discoveries of M. Berthelot, and the long and glorious labours of M. Cahours.

July 15, 1867.

Pre-Newtonian ideas of gravitation—Marine Engines—Election of M. Wurtz *as a Member of the Academy—Perfluoride of Manganese—Isolation of Fluorine—Oxychloride of Magnesia to replace Plaster of Paris.*

M. Chasles laid on the table the letters and notes from Pascal alluded to at the last meeting. It is incontestable that in these autographs, the date of which is certainly anterior to 1662, the year of the death of Pascal, the illustrious philosopher speaks of attraction at a distance as well as at the surface of the earth and in the midst of the celestial spaces, and even of molecular attraction, in the same terms as Newton. He makes the same calculation of bodies falling in an orbit, of mass, of distance; he lays down the same laws, etc.

M. Du Puy de Lome made a long and interesting communication on the marine engines of the ship of war Friedland, of the French navy, with three cylinders and of 1,000 nominal horse-power, and an effective power of 4,000, which will give the ship a speed of fourteen knots an hour with sixty revolutions of the screw per minute.

The academy then proceeded to the election of a member in place of M. Pelouze. The number voting was 53; M. Wurtz was elected with 45 votes against 3 given to M. Berthelot, and 2 to M. Cahours. It is, as we have before stated, almost the unanimity of votes; there were two blank billets, that is to say, that two of the illustrious did not consider MM. Wurtz, Berthelot, and Cahours worthy of sitting beside them, and did not give themselves the trouble of choosing between them. It is melancholy to see academicians imbued with feelings of such a foolish disdain, or evincing publicly so great a meanness of spirit.

M. Dumas announced that M. Nicklès, of Nancy, had just made a discovery in mineral chemistry by showing how to prepare a combination of fluorine and manganese, which is to the simple fluoride what the binoxide of sesquioxide is to the simple oxide, the protochloride, and the protoidide to the deuto, sesqui, or polychloride, or iodide. M. Nicklès has found that the new combination, deutofluoride, or fluoride of fluoride of manganese, is less stable than the analogous chloride or iodide. Moreover, and this gives great importance to the discovery, the deutofluoride will certainly be less stable than the simple fluoride of manganese, and it seems difficult to believe that we shall not one day succeed in decomposing it by heat, or otherwise, into fluorine and fluoride of manganese, under conditions which will permit the fluorine to be isolated, and so fill up a great gap in chemistry.

M. Dumas then called the attention of the academy to a new industry of M. Sarel, which nothing could lead us to foresee, viz., that chloride of magnesium can unite and associate with magnesia or oxide of magnesium to form an oxychloride of magnesium perfectly insoluble, and possessing, as does the oxychloride of zinc, in a degree incomparably greater than plaster of Paris, the property of not only taking all variety of forms, but of causing the solidification and taking a high polish of a great number of substances with which it may be mixed, in the proportion of a fifteenth to a twentieth of their weight. Experiments made two years ago leave no doubt on the good quality of stones prepared by this process, and the absolute resistance, of objects so fabricated and moulded, to the deleterious action of water. Industry and art will therefore enter into possession of new elements of construction and transformation. The chloride of magnesium that can be extracted from sea water, or which is found in great quantities solidified in interior seas as that of Stassfurth, does not require to be entirely pure, and costs less than the oxychloride of zinc.

NOTICES OF BOOKS.

MINERALOGICAL PAMPHLETS.

An Index to Mineralogy. By T. Allison Readwin, F.G.S., F.S.S., etc. London: E. and F. N. Spon, Charing-cross.

Royal Agricultural College, Cirencester. A Guide to the Chemical Department of the College Museum. Part I. The Mineral Collection.

Sketch of the Mineralogy of Nova Scotia, as Illustrated by the Collections of Minerals sent to the Paris Exhibition, 1867. By Professor How, D.C.L., University of King's College, Windsor, N.S. Published by authority of the Commissioners for Nova Scotia.

Mr. Readwin, in the preface, states that the list is obviously imperfect, and that he hopes it will elicit correction at the hands of chemists and others. The index is a list of some 2,500 minerals, with synonymes, the constituents expressed by contractions in a small space, and the number of the case in the British Museum containing specimens. We take an example showing the method Mr. Readwin employs:—

"Eulysite (chrysolite) Mg. Sil. B. M. 36 (var. Olivine.)"

By an explanation at the commencement of the book the student finds eulysite to belong to the same species of mineral as chrysolite. The remainder of the information with regard to the mineral is evident at once.

It is a little work which will be appreciated by those interested in mineralogy.

The aim of the writer of the second pamphlet—Professor A. H. Church—is merely to describe the more important minerals to be found in the museum. There is no attempt at being encyclopædic. The minerals are classed under six divisions, and the most important mineral species belonging to each division are pointed out. The information is given in a very clear and concise manner, and were it not published in the form of a guide, we should be inclined to call it brief to a fault.

It is stated by Professor How that the collections of minerals made on the present occasion are sufficient evidence that the mineralogy of Nova Scotia is very interesting, both from a scientific and an economic point of view. In the first place gold is obtained in considerable quantity. Very valuable iron ores are also worked, ores yielding bar iron which ranks with the finest Swedish metal for making steel. Ores of manganese are worked, and the value of that sent from Teny Cape up to the present equals £8,000 or £9,000. Wad, manganite and pyrolusite are exhibited. Native copper and other ores are to some extent worked. A variety of copper ores are exhibited, copper pyrites, cupriferous oxide of iron.

Galena is also represented from several localities. Mispickel is also exhibited from three or four localities, and is sometimes found in large amount; cobalt occasionally occurs with it. Barytes occurs in some places in sufficient quantity to be exported. Gypsum exists in inexhaustible profusion; natroborocalcite, and a mineral containing 59 per cent. of boric acid—cryptomorphite—have been found embedded in it. Both are exhibited. Anhydrite occurs in quantity. Other products are marble, limestones, granite, sandstone, etc. The author, we think, certainly proves his opening statement.

The Alkali Act, 1863. *Third Annual Report by the Inspector, of his Proceedings during the Year* 1866. By Dr. Angus Smith, F.R.S., etc., Government Inspector.

It is gratifying to find that Dr. Angus Smith is able to state in this, his third report, that there has been a further advance in the manner of preventing the escape of muriatic acid gas; and that, although during the last year the escape has been greater in the actual number of tons, it is owing to the increase in the manufacture. The amount of salt decomposed during the first year of inspection was 288,000 tons, during the second 310,000, and during the third it is 371.950. The necessity for inspection is well borne out by many of the facts related in connection with them.

For instance, in one case, where there appeared to be all the ordinary contrivances for condensation, 20·5 per cent. of the muriatic acid was found to be escaping. Another test, taken after alterations had been made, with a view of checking the escape, showed the presence of 13·5 per cent. The owner was prohibited from working with these arrangements. He stopped work, and erected a second condensing tower, but the escape was still 15 per cent. The inspector again prohibited work until a remedy was found. The arrangements ultimately were properly made, and at a subsequent inspection the escape was only 1 per cent. Dr. Angus Smith writes—"The struggle with the condensers may be said to have ceased; the circumstances are understood. Our new struggle is with this escape from the works, and of a certain amount of gas which passes through bricks, tubes, and even stone, as well as of that coming occasionally from the mouth of the furnace."

The author remarks upon the way in which the manufacturers have come to regard inspectors. Finding that in many manufactories there was not a sufficient staff with chemical knowledge, the inspector has given advice with regard to the alterations required, and if the changes have been speedily made, has refrained from prosecution. A letter from a manufacturer illustrates the feeling referred to. In the course of it he writes: "It is very annoying to me that you should ever find anything to find fault with, but as our method of working is uniformly the same, and as we have no means of knowing when the condensation is right except from your tests and inspections, I hope you will not be long before you come again, and, if possible, often." The author of the report says: "I consider this letter an indication that the time has now come for throwing aside much of the responsibility which we have taken from the manufacturers, or they will turn round to throw on us the blame of any infraction of the Act committed in their own works." It would appear that the proprietor found that in the visits of the inspector he obtained such valuable advice as to save him the expense of attaching a chemist to his establishment. No doubt great good has been done by the excellent spirit in which the inspections have been made, but now that manufacturers are making greater profits by the larger amount of acid they are enabled to obtain from the same amount of material, and likewise by the saving in many cases of the amounts formerly paid as damages, we consider that Dr. Angus Smith, and those gentlemen under his direction, have no longer any need to burden themselves with duties which, as inspectors, they were in no way bound to undertake. The author is evidently not inclined to a radical change in this direction, as the following extract in reference to the peremptory demand of good condensation shows:—"When the habit of condensing or of destroying all noxious vapours has been longer confirmed, this demand may grow to be just and reasonable." In another place he remarks that if the number of works under the inspectors were much increased, there would be no time left in which to consider and advise manufacturers. At the end of the report are a few pages devoted to the consideration of what is meant by a nuisance.

Dr. Angus Smith shows, we think very clearly, an advantage of inspection. This, although a minor one, is of great importance to manufacturers, as they possess one interest, and the public another. It is in reference to the subject of a *nuisance*—a word conveying an excessively vague meaning—that the author draws attention. At present, he says, excepting those factories coming under the Alkali Act, the public are not protected from the manufacturer, neither is the latter protected from the public. Take, in the first place, the case of a housholder who suffers from the escape of noxious gases evolved from a nest, such as in London is found at Belle Isle. The processes, which may be bad enough when properly carried on, are probably clumsily managed. He must of course be able to fix the nuisance upon a particular factory, and this is one great difficulty. In such cases the evidence is characterised by great uncertainty; even a chemist, as Dr. Angus Smith says, is frequently obliged to trust chiefly to his senses, as he cannot obtain admission to the factory, and therefore the gases may be so diluted where he examines the air as to make it difficult to prove their presence. The following sentence, occurring in the report, exactly expresses our own opinion upon this point:—

"The want of protection to the public lies, in ordinary nuisance cases, in the want of power to enter the works and to make experiments."

In another place the author writes, "Unless chemists can define a nuisance, and have opportunity of examining in cases of complaint, neither the public nor the manufacturer is protected."

Taking now the case of a manufacturer, a case is stated showing that he is liable to be attacked and injured unjustly:—

"It sometimes happens," as the author puts it, "that a neighbour who is peculiarly sensitive, objects to the smell of even well-conducted works; he may be able to say truly that they are to him very offensive, and he may have no idea that, were all men to have an equally acute sense of smell, manufactures would cease. He may, however, care little for such things, and be determined to seek his own comfort only, and he, therefore, on oath and with truth, says that the smell makes his house unpleasant."

The laws referring to nuisances, we are told, are also vague, owing to the want of precise modes of detecting them.

This is not the case with those which come under the Alkali Act. Here there is complete protection up to a certain point, to both manufacturers and the public. We quote once more to give the opinion of the author, who is necessarily an authority, upon this point. He says:—"It seems to me that the system of inspection protects both sides if the inspector has his direct instructions, as under the Alkali Act, to look for the condensation of a distinct amount. The public is freed from 95 per cent. of muriatic acid by this Act, and the manufacturer is protected from the complaints of the public so far. If a similar fixed point could be adopted in the case of every gas, there would be complete protection to the public and manufacturer on both sides up to that point, occasional mistakes and accidents excepted. It seems to me a most important thing to seek such fixed points, and where they cannot be attained to make the nearest approach to them, so that evidence may be taken by competent persons on the spot, instead of by persons stretching at some distance beyond the works the capacities of their sense of smell."

The Act referring to the manufacture of hydrochloric acid has worked so well that we would urge upon the Government the necessity of the inspection of all similar manufactures. There can be little question that the Alkali Act has resulted in benefit to the manufacturers who were brought under its influence. Imagine a manufacturer of hydrochloric acid (we are willing to believe it an exceptional case) allowing an escape of 20 per cent.!

In an appendix Dr. Angus Smith describes an apparatus, and the method of using it, for the determination of the speed of air in flues. We must refer those of our readers who may be interested to the original, as the paper is long, and not capable of condensation.

CORRESPONDENCE.

A Lecture Experiment.

To the Editor of the Chemical News.

Sir,—The following simple apparatus which I contrived lately for illustrating the manufacture of sulphuric acid, may be interesting to some of your readers. Three tubes are passed through the cork of a wide-mouthed bottle, the largest being connected by an india-rubber junction with a pint funnel, and the small one to the left with a test-tube generating NO by means of copper turnings and nitric acid. The middle tube admits air. A little water is poured into the bottle first, to combine with SO_3 for the production of H_2SO_4. The funnel is covered in with a metal cap to which a small pan is suspended. This pan is a miniature furnace. A bit of sulphur is placed in it and lighted. The fumes of SO_2 immediately flow down in a conspicuous stream into the bottle. Here they encounter NO, and the usual reaction takes place. Any SO_2 which the water may dissolve is expelled by boiling, when the solution answers to all the tests for the presence of sulphuric acid. An extra cover which slides on the metal lid, conceals some air-holes, useful at the beginning of the experiment. Hoping this modification of the apparatus described by Miller for a similar purpose, may be acceptable as an exact and economical imitation of a most interesting manufacturing process,

I am, etc., E. S.

Nottingham, June 6, 1867.

Extinction of Fires.

To the Editor of the Chemical News.

Sir,—Will you allow me to make a few remarks respecting a fire which took place the other day in an oil distillery at Hackney Wick? I happened to be passing at the time, and watched the progress of the flames. We all know that from whatever cause a fire takes place, water is rushed to for putting it out. In the case I refer to, the place was, as usual, drowned with water, which merely had the effect of spreading the flames and increasing their intensity, for the oil burned until there appeared to be nothing left to support the flames. Now my reason for sending you this letter is to point out how easily this fire might have been put out if a simple plan, which I shall mention, had been adopted, and there is no doubt that many similar fires could be extinguished by the same means. At the fire referred to I noticed the flaming oil floating on the surface of the water on the floors. The water running down the walls bore a flaming surface of oil likewise. This shows that the water had little or no power over the burning oil.

There was lying near the building in which the fire broke out, a large quantity of sand. Now if half-a-dozen men, provided with spades, had "dashed" a lot of this sand upon the flames soon after the fire was discovered, I have no hesitation in saying that it would have been put out, and but little damage done. But this was not the case, for long before the engines arrived, the fire had got such a hold upon the building and its contents that the firemen's work was little better than labour in vain, for the place was completely gutted. The sudden throwing of sand or any similar substance upon masses of flame proceeding from burning oil, etc., is generally sufficient to extinguish or choke them out.

Some time ago I put out a fire, which might have destroyed an immense amount of valuable property, by simply dashing fifty or a hundred shovelfuls of slaked lime, which happened to be near at hand, upon the flames, which literally choked them out. The fire in this case was caused by a cask of oil being set on fire accidentally. This is only one of the many fires which I have seen put out by adopting the same means. I consider it would be a good plan if owners of such places as oil works, etc., always had at hand a quantity of sand, dry old lime waste, etc., which could be used in the manner I have stated when necessary.

I am advancing no fancy statement, but giving your readers a plan which has been tried with every success, and I could write much in favour of this plan did I think such a course at all necessary.

I am, etc., T. H. Swindells,
Consulting Chemist.

July 2.

Use of Distilled Water.

To the Editor of the Chemical News.

Sir,—In Mr. Quin's report upon the Paris Exhibition, reference is made to the use of distilled water at the Wallaroo Copper Mines in South Australia, stating that until tanks for collecting rain-water had been constructed, "perhaps for the first time in the history of the world, there was a population of some thousands, with all their horses, cattle, sheep, etc., drinking *aqua distillata*." As many of your readers may not be aware of the fact, it may be interesting here to mention that in the rainless region of the Pacific coast of South America, the entire population of the country, between about the 18th and 28th parallels of south latitude, or some 600 miles from south to north, including the important towns of Caldera, Cobija, Iquique, Pisagua, and several minor ports, have for many years derived their supply of potable water from the sea water of the Pacific, distilled in greater part by coal imported from England and costing above £3 per ton.

Not only is a population of many thousand inhabitants, principally engaged in the mines of this district, as well as a still larger number of beasts of burden, and other animals, supplied from this source, but even the locomotives on the Copiapo and Caldera railway, and some steam engines for other purposes, are actually driven with distilled water. For a distance of some thirty to fifty miles inland from the coast, very few natural springs are met with in this rainless desert, and when met with they are seldom sufficiently free from saline matter to be potable. D. F.

Magnetism and Gravitation.

To the Editor of the Chemical News.

Sir,—The paper by Mr. Newlands appears to me to be based in great part, if not entirely, on erroneous notions regarding magnetism.

If the distance between the pole of a magnet and a magnetic body is very considerable as compared to the size of the latter, the body will not be attracted, inasmuch as two opposite poles are always produced by induction; and as, under the above conditions, both these induced poles may be regarded as at the same distance from the inducing pole, the one will be repelled exactly as strongly as the other is attracted, the result, as regards attraction, will therefore be *nil*. The distance of the poles of the earth being almost infinite compared to the size of a piece of iron on the pan of our balance, the iron will not be attracted by the magnetic power of the earth, and will weigh as much on the equator as on the poles, subject only to the altered force of gravity. I am, etc., A. D.

Vapour Density of Water.

To the Editor of the Chemical News.

Sir,—The apparent discrepancy between the two modes of calculating the expansion of water in becoming steam noticed by Mr. F. O. Ward, in your last number, arises from a slight error in one of the calculations, which should be as follows:—

	Grammes.
2 litres of H at 0·08936[*] = ...	0·17872
1 litre of O at 16 × 0·08936 = ...	1·42976
	1·60848

The 3 litres being condensed into 2, a litre of aqueous vapour at 0°C. and 760 mm. weighs .... $\frac{1{\cdot}60848}{2} = 0{\cdot}80424$

and hence (neglecting the slight expansion of water in cooling from its point of maximum density 0°) 1 litre of water at 0° would become $\frac{1000}{0{\cdot}10424}$ or 1243·4 litres of aqueous vapour. The steam, however, being formed at 100°, will become expanded to $\frac{373}{273} \times 1243{\cdot}4$ or 1,699 litres, so that again neglecting the slight expansion of the water in heating from the point of maximum density to 100°, 1 litre of water at 100° becomes 1,699 litres of steam at 100°.

The vapour density of water (observed, air = 1·0000), and the weight of a litre of air at 0° and 760 mm. as given in Cooke's *Chemical Physics*, p. 693, are respectively 0·6235 and 1·29206 grammes: hence the weight at 0° and 760 mm. of a litre of aqueous vapour will be 1·29206 × 0·6235, or 0·8056 grammes, which does not differ much from the previous theoretical number 0·80424, and corresponds to an expansion at 100° of 1,696 times since $\frac{1000}{0{\cdot}8056} \times \frac{373}{273} = 1{,}696$.

—I am, etc.,

Charles R. A. Wright, B.Sc.

Chemical Laboratory, St. Thomas's Hospital,
July 13th, 1867.

To the Editor of the Chemical News.

Sir,—The few editorial remarks which appeared in your issue of the 12th inst., induced me to look over Mr. Ward's statements on the above-named subject. I think I may safely advance that Mr. Ward has erred in this instance to the extent of the difference indicated between his numbers and the experimental results. Adopting the specific weights which he gives for the volume of the water constituents, the weight of a litre of steam at 0°C., and ordinary pressure, would not be 7·2576 grms., as Mr. Ward states, but 0·8064 grm. It follows, therefore, that a litre of water would produce a volume of steam at 100°C., which, when corrected to 0°, would amount to

$$1241{\cdot}3 \text{ litres } \left(\frac{1000}{0{\cdot}8064} = 1241{\cdot}3\right).$$

According to Mr. Ward's figures this volume should be 137·77 litres $\left(= \frac{1000}{7{\cdot}2576} = 137{\cdot}77\right)$, although he enlarges the result to 1377·8 litres.

Gay Lussac's experimental determination of 1,700 litres as the volume a litre of water acquires when converted into steam by a temperature of 100° if corrected to 0°C. corresponds very nearly with the volume of 1241·3 litres, for $\frac{1700}{1{\cdot}3665} = 1244$.

The corrections to 0° cannot make any important difference in the ratios; and I may state that the relation of volumes deduced by theory, or obtained by experiment, would be coincident at any point intermediate between 0° and 100°. So far, therefore, we may believe that perfect harmony exists between the theoretical and experimental results in relation to the expansion of water into steam at 100°.

Indeed, it is beyond my capacity to comprehend how any difference could arise here between theory and experiment, or that in the entire series of volume-ratios any discord or diversity could be educed under similar or analogous conditions to those referred to.—I am, etc.,

Martin Murphy.

College of Chemistry, Liverpool, 13th July, 1867.

To the Editor of the Chemical News.

Sir,—The assertion that water expands 1696-fold in becoming steam at 212°F., rests on the authority of Gay Lussac, and is a result of direct experiment. He found that 1 c.c. of water gives 1626·4 c.c. of steam measured at 100°C.

Now, 2 litres of H weigh....................	0·1792
1 —— O ——	1·4336
	1·6128

1 litre of steam at 0°C. weighs, then, 0·8064 grm. Hence, 0°8064 c.c. water at 4°C. becomes 1000 c.c. steam at 0°C. and 1367 c.c. at 100°C., or 1 c.c. water becomes 1695·2 c.c. steam at 100°C.

The difference between theoretical and experimental results amounts thus not to 8 per cent. but to 0·08 per cent.

There are three errors in Mr. Ward's calculations, which, however, counteract each other rather curiously.

$16 \times 0{\cdot}0896 = 1{\cdot}4336$, not 14·336

$\frac{1000}{7{\cdot}2576} = 137{\cdot}78$ not 1377·8

I am utterly unable to understand the method adopted for the correction for temperature. I may remark, however, that the coefficient of expansion of gases for 1°F. is

$$\frac{1}{491} \text{ and not } \frac{1}{460}$$

and that the correction should be made from 212°F. to 32°F., and not to 60°F.—I am, etc.,

W. M. Watts, D.Sc.

Glasgow, July 16th, 1867.

To the Editor of the Chemical News.

Sir,—I observe some calculations under the above heading in this week's Chemical News. If Mr. Ward had made his calculations correctly, he would have had no difficulty in reconciling the fact that water expands 1·696-fold when converted into steam at 212° F., with the vapour density of water.

It is not necessary to point out all the errors of calculation. The following calculations will show most of them when placed in juxtaposition, and it is only necessary to state that the weights of hydrogen and oxygen are taken from "Bunsen's Gasometry."

	Grammes.	
2 litres of H at 0·08961 = ...	·17922	at 32° F.
1 litre of O = ...	1·43028	"
2 litres of water vapour = ...	1·60950	"
1 litre of do = ...	·80475	"

$$\frac{1000}{{\cdot}80475} = 1242{\cdot}6$$

$1242{\cdot}6 \times 1{\cdot}3665 = 1698{\cdot}0$ = volume of vapour at 212° F., from unit of water of maximum density (at 39·2° F.). 1,696 has probably been arrived at by cutting off fractions; by multiplying 1,242 by 1·366 we get 1696·5.—I am, etc.,

D. H.

To the Editor of the Chemical News.

Sir,—In Mr. F. O. Ward's calculation of the vapour density

---

[*] The weight in grammes of a litre of hydrogen at 0 deg. C. and 760 mm. pressure.—*Roscoe's Chemistry*, p. 19.

of water a mistake occurs, which, if corrected, will remove the discrepancy noticed by him.

$$\begin{array}{lrcl} & & & \text{Grammes.} \\ \text{2 litres H at} & 0{\cdot}0896 & = & 0{\cdot}1792 \\ \text{1 litre O at} & 16 \times 0{\cdot}0896 & = & 1{\cdot}4336 \\ \hline & & & 1{\cdot}6128 \end{array}$$

3 litres becoming 2 we have $\frac{1{\cdot}6128}{2} = 0{\cdot}8064 = 9 \times 0{\cdot}0896$ as the weight of one litre of steam at 0°C., and 760 mm. pressure. A litre of water weighing 1000 grammes, at 4°C. or 999·88 grammes, at 0° will therefore give

$\frac{999{\cdot}88}{0{\cdot}8064} = 1239{\cdot}9$ litres steam at 0°C. and 760 mm. pressure.

Reducing the alleged 1·696 litres at 100° for temperature, we get $\frac{1696}{1{\cdot}307} = 1240{\cdot}6$ litres at 0° and 760 mm. pressure, or almost exactly the theoretical quantity, assuming steam to possess the same coefficient of expansion as atmospheric air, viz., 0·367 between 0° and 100°, and under constant pressure. The *crith*, it should be remembered, is the weight of a litre of gas or vapour at 760 mm. pressure, and at 0°C., and not at 60°F.—I am, etc.,

A. D.

Vapour Density of Water.—"Chemistry of the Future."

To the Editor of the Chemical News.

Sir,—I notice, with not unpleasurable surprise, that you have bestowed the honour of publicity on some remarks of mine, not penned with a view to impression, and wanting, I see, some little revision. They refer to the discrepancy of the figures representing the vapour density of water, as on one hand deduced from its received volumetric constitution, and as computed, on the other hand, by correcting, for temperature, the ordinary statement of the expansion of water in becoming steam at 212°F., viz., 1696-fold. The accidental misplacement of a decimal point, and a casual error in the reduction of boiling point to 60° F. have led to the working out of the discrepancy as greater than it really is. I subjoin the corrected figures, from which it will be seen that the discrepancy is still large; leaving me nothing to alter in the remarks founded thereon.

Computing the vapour density of steam from its volumetric constitution, we have:—

$$\begin{array}{ll} \text{2 litres of H}=1 \text{ at } 0{\cdot}0896 \ldots\ldots\ldots\ldots & 0{\cdot}1792 \\ \text{1 litre of O}=16 \times 0{\cdot}0896 \ldots\ldots\ldots\ldots & 1{\cdot}4336 \\ \hline \text{3 litres weighing} \ldots\ldots\ldots\ldots & 1{\cdot}6128 \end{array}$$

These 3 litres being condensed into 2, we have

$$\frac{1{\cdot}6128}{2} = 0{\cdot}8064$$

as the vapour density required. As a litre of water weighs 1000 grammes, its expansion ratio, in becoming steam at ordinary temperature and pressure, is obviously

$$\frac{1000}{0{\cdot}8064} = 1240$$

Turning now to the usually alleged expansion-ratio, 1696, and reducing it for temperature, at the rate of $\frac{1}{460}$ per degree F., for the difference between boiling point and 60°F.=120°, we have the ratio

$$\begin{array}{ll} \frac{340}{460} \times 1696 = \ldots\ldots\ldots\ldots & 1253{\cdot}5656 \\ \text{which, set against the above computed} \ldots\ldots & 1240{\cdot}0000 \\ \hline \text{Shows a discrepancy of} \ldots\ldots\ldots\ldots & 13{\cdot}5656 \end{array}$$

This is the point to which I called my friends' attention, with reference to the question whether the volumetric relations of bodies are so symmetrical as is our present disposition to suppose.

This touches a subject now strongly attracting the attention of the chemical world—I mean the nature and constitution of matter and the mode to be preferred of conceiving and representing its chemical transformations. With reference to these deeply interesting questions, I will ask your permission to cite here a letter which I received, more than 20 years ago, from Professor Faraday. I was at that time a youth at college, in the first ardor of my scientific studies, and I had devised—as most chemical tyros do, I believe— a fantastical theory of the nature of matter and of the forms and properties of its elementary particles, as also of the building up of these into compound molecules. No doubt I made my acid particles pointed and my sugary and oleaginous molecules round, taking care to provide my atoms with suitable facets whereby to fit one another in the construction of compounds, all which ordinary fluttering of my young chemical wings I must have deemed vastly profound and original, since I posted the paper, with high expectations, for the illustrious professor's judgment.

Two days afterwards I received a letter, on the corner of which I read, with a beating heart, the celebrated philosopher's signature. Being at present far away from my archives, I can but quote this letter from memory, yet I think I can give it to you nearly *verbatim*, so profound was the impression made on my mind by its modest simplicity, contrasted with my boyish presumption, and so lasting was the philosophic lesson it conveyed. It ran nearly thus:—

"I have received your ingenious speculations on the nature of matter, and on the forms and properties of atoms; and, in reply to your question, I have no hesitation in advising you to experiment in support of your views, because whether they be confirmed or confuted, good always comes of experiment.

"As to your views themselves, and my own opinion on the subject, I am fain to confess that I have thought long and closely on the theories of matter, and on the nature of its particles or atoms; and that the more I think, in association with experiment, the less distinct does my idea of an atom or particle of matter become."

I have never known which most to admire in this letter—its modest wisdom, or the condescending kindness which prompted its writer to bestow on an obscure youth—to him a total stranger—so gentle yet impressive a monition.

But why is it cited now and here?

Because its marking words—"*in association with experiment*"—are if I mistake not, particularly apposite to the present posture of chemical affairs.

The chemical world is, indeed, under invitation to embrace a new theoretic system, which incorporates, as an essential part of its fabric, the affirmation that several bodies, never yet decomposed, are compounds of a known with certain unknown elements; and, further, as regards the known elements themselves, that they are the results, some of one, others of two or more "*operations*," strangely likened to so many "strokes on a bell."

It would ill befit a mere student, like myself, of some of the simpler parts of chemistry, to criticise proposals brought forward by a recognised master of the science. Yet my admitted inferiority leaves me all the freer to confess that my dim conceptions of elementary matter derive no light from the suggestion that, in a "chemical operation," the evolution of hydrogen is attended, as it were, with *one* sound, and that of oxygen with *two*.

So, again, I may frankly avow that, to me, the proposed substitution of Greek for Roman letters, in our chemical symbols and formulæ, seems likely to impart to our hitherto attractive science, an aspect of abstruseness uncompensated by any *real* addition thereby made to the profundity of our knowledge.

Our real experimental acquaintance with the nature and constitution of hydrochloric acid, for example, remains unaltered, so far as I can see, whether we write it HCl, as of old, or denote it by the Greek symbol, $\alpha\chi$: and, for my own part, I feel the deep mystery of chlorine undiminished, when I am told, as the result of a series of equations, that

$$\chi = \frac{Cl}{H}$$

Still less, methinks, can the clearness of our physicochemical conceptions and reasonings be promoted by the two-fold interpretation which it is proposed to bestow on the algebraic signs + and —. These, it would seem, we are invited to employ, sometimes in their old accustomed acceptation, sometimes as symbols of differences in "direction;" which differences, an arrow-head turned this way or that, would, I think, much more fitly represent.

By an equally gratuitous confusion of things different, the ordinary collocations signifying in algebra multiplication and division, are to be henceforth employed by chemists, not in those familiar senses only, but also as signs of chemical combination and decomposition. For my part, I must confess that I cannot trace the faintest analogy between the multiplication of one number by another, and the combination of two chemical elements; though here confusion can scarcely be avoided, the algebraists having unadvisedly as I think, made the mere writing of two quantities in immediate succession the sign of their multiplication into each other. No such necessity can be pleaded to justify the use of the symbolic grouping $\frac{a}{b}$, heretofore set apart to express the division of one quantity by another, as the sign of so utterly dissimilar a conception as that of chemical decomposition, which we are, nevertheless, invited to write in much the same manner—putting $\frac{Cl}{H}$, for instance, to signify the decomposition of hydrochloric acid. If symbols of chemical combination and severance be needed, why not devise some simple forms of expression for the purpose; as, for example, marks of parenthesis, ordinary and reversed, the former for combination—(HCl), the latter for decomposition—H)(Cl. Surely this, or some equivalent expedient, would be more philosophical than the forcing into an artificial quasi-connexity, of facts and conceptions so utterly incongruous as to be absolutely incomparable.

I own myself at a loss to discover the additional profundity of reasoning assumed to be derivable from this ambiguous duplication of the meaning of symbols hitherto received, each only in a single sense. This mixing up of algebraic and chemical symbols, so far from assisting ratiocination in either kind, will rather tend, I think, to increase the toil of chemical thought and to multiply the chances of chemical error, by the additional stress gratuitously imposed on the chemist's attention, thus called on, as it will be, to catch correctly so many alternating modes of interpretation, each in its variable turn.

As for the new "fundamental definition" of a chemical phenomenon, it is "an operation on the unit of space, the result of which is a weight" I confess that, for me, this play of words throws not the faintest ray of light on any of the familiar marvels of chemistry, such as solution, effervescence, crystallisation, explosion, and all the numberless transformations of form, colour, combination, properties, etc., which collectively make up our astonishing science. In what sense is the above definition more luminous, more explanatory of the wonders amidst which we move, than if one should say, conversely, that a chemical phenomenon results from the operation of a weight (or weights) within given limits of space (and time). There is no limit to the multiplication of such abstractions, and if that now propounded gains acceptance, I cannot see why, to-morrow, a new Transcendental school may not be started, with a modified "fundamental definition," declaring a "chemical phenomenon" to be an "operation upon the unit of Time, the result of which is a Force."

Such expressions may be more or less neat and antithetic, but they afford us not the slightest insight into those hidden ways of nature which they affect to fathom and reveal. The *essence* of natural phenomena is, indeed, unknowable; we may study their relations, and ascertain the conditions of their existence, so as to obtain means for their modification and control, but when we seek, with subtle phrases, to express their absolute nature and causation, we do but disguise our ignorance and cheat our yearning curiosity with words. Of such kind appears to be the abstract definition of chemical phenomena now put forward to fit our science for the new analytical method proposed; and unless this apprehension should prove to be ill-founded, the new system will do little, I fear, towards promoting the real inductive progress of chemistry.

Far be it, however, from me to deprecate the introduction into chemical science of any high analytical method, if such there be, really compatible with its eminently concrete and experimental character, and really calculated to support the arduous reasoning of chemists through further-reaching concatenations than have heretofore been possible for them. But no such transcendental methods will avail, unless, as Faraday enjoins, they be used in constant "association with experiment," and due subjection to its wholesome check.

This rule would, I think, be as seriously infringed by the premature acceptance of chlorine, and a series of cognate bodies, as compounds of hydrogen with various unknown elements, as it would have been, if, in Sir Humphrey Davy's time, the suspected composite character of the alkalies had been elevated to the dignity of an established fact before its reality had been demonstrated by Davy's ever memorable experiments.

I would not, however, be understood as seeking, by any means, to undervalue or disparage the intellectual power displayed by the eminent propounder of the new doctrine, in his vigorous assault on the so-called "Chemistry of the Past," and equally cogent demonstration of the necessity for a higher and larger "Chemistry of the Future." In this proposition all chemists are, I think, agreed. It has long been felt by philosophical reasoners—Auguste Comte among the number—that the atomic theory fails to satisfy our intellectual requirements, when it is applied to the interpretation of *organic* chemistry, though it has answered its purpose admirably as a means of intelligibly connecting the main facts of *inorganic* chemistry. We, therefore, need a unitary conception, of more comprehensive scope, capable of embracing, under common forms the facts of both divisions of the science, and adapted to make manifest their intrinsic harmony, not only with each other, but also with the recent developments of physical science, such as, for instance, the lately proved convertibility of motion into force, and *vice versa*.

It is not, therefore, in any captious dislike of innovation, still less in a cavilling or disrespectful spirit, that I have ventured to submit what seem to me objections to the system now proposed. My attitude is rather that of a student who, after a perplexing lecture, lays his doubts, with deference, before his professor. I feel anxious lest chemical philosophy, at this juncture, should be led into a false, though brilliant path; lest, in striving after analytical methods, possibly unsuited to a science so essentially concrete and experimental, we should barter solid facts for metaphysical subtleties, and only, after all, make chemistry more abstract, at the cost of making it less real.

Like my chemical betters, however, I await, before finally judging the new system, its full and complete development; and I shall be found among its first and most grateful devotees, should it open up new spheres of really *positive* reasoning and research, and tend to facilitate (in Faraday's pregnant phrase) "THOUGHT ASSOCIATED WITH EXPERIMENT."

F. O. WARD.

VAPOUR DENSITY OF WATER.

To the Editor of the Chemical News.

SIR,—I have read with much interest the five communications called forth by some remarks on the vapour density of water, extracted by you from a letter of mine to a private friend.

It is curious to note the little discrepancies which occur in the computations of so many able and learned men applying their minds to the same subject.

On one point the five letters supply these different figures:—

·80424 ·80475 ·8056 ·8064,

of which the last-named has the support of the majority, and is the figure at which I had previously arrived.

On another point I gather these figures:—

1239·9 1240·6 1241·3 1242·6 1243·4—

my own figure, independently calculated, being 1240.

On the question of the true gas-expansion ratio, touched by one of your correspondents, and lying at the very root of the matter, I happen to have a paper at hand, giving the results arrived at by several eminent authorities, and showing notable discrepancies between them, even as to this fundamental *datum*. These ratios are as folows, for the volume at zero F.:—

Dalton and Gay Lussac	$\frac{1}{448}$
Regnault	$\frac{1}{458}$
Magnus	$\frac{1}{459}$
Rudberg	$\frac{1}{462}$

Correcting these ratios for the volume at freezing-point, they become:—

Dalton and Gay Lussac	$\frac{1}{480}$
Regnault	$\frac{1}{490}$
Magnus	$\frac{1}{491}$
Rudberg	$\frac{1}{494}$

Applying the first and last of these ratios to the question in hand, and taking $\frac{1000}{\cdot 8064} = 1240$ as the standard for comparison (my own computation whereof is sanctioned by the majority of your correspondents), we have, according to Dalton and Gay Lussac—

$$\frac{480}{660} \times 1696 = 1233{\cdot}45$$

and, according to Rudberg:—

$$\frac{494}{674} \times 1696 = 1243{\cdot}06$$

On comparing each of these results with our above-mentioned standard, deduced from the volumetric composition of water, we obtain, as the respective discrepancies, *the values* 6·55 and 3·06; the former being *below* and the latter *above* the standard; so that the discrepancy between the two results themselves is the sum of the amounts above stated, viz., $6{\cdot}55 + 3{\cdot}06 = 9{\cdot}61$.

Neither of these discrepancies, however, is so large as that worked out by me in my last letter—into which, I must own, that error crept, through my using (in the absence of my books of reference) an imperfectly remembered rule of computation.

If lastly, we work out the calculation as before, substituting Regnault's ratio, we obtain

$$\frac{490}{670} \times 1696 = 1240{\cdot}3582$$

which differs from the standard by only

0·3582.

The question therefore turns, so far as the greater or less discrepancy is concerned, upon the relative merits of the respective determinations, by the eminent authorities quoted, of the expansion ratio for gases: as also, upon the more or less thorough soundness of the laws laid down as governing the expansion of gases, one or two of which laws, if I remember rightly, rest partly on assumption.

Meanwhile, though we are free to regard the discrepancy under consideration as larger or smaller, according to the expansion ratio on which we elect to rely, science as yet affords no absolutely certain proof, entitling any one to deny its existence.

The observed and calculated vapour-densities of many other bodies, besides water, show also (unless my memory betrays me) fractional differences more or less important, the very smallest of which may have a real existence, and may exercise more influence than is yet suspected on the play of chemical phenomena. This was the special consideration I addressed to my friend—supporting it by an example drawn from water, and an analogy supplied by music. In the carelessness of intimate pen-talk, I inadvertently made out the discrepancy cited too great; and this, not only as regards the fact itself, but also as regards the fitness of the illustration to my argument. For I was really referring to minute, not considerable differences: and my example is rendered all the more apposite by the correction now supplied.

The want of symmetry established, by Stas, in the ponderal relations of matter, lends colour, I think, to the hypothesis, that a like condition may attend its cognate volumetric proportionalities: for, that these relations should be all absolutely integral, while so many of the others are fractional, seems to me a somewhat hazardous assumption.

In these musings, however, I carefully avoid affirmation; I merely ponder and surmise. Such unripe germs of thought are fitter, no doubt, for the commerce of friends than for the wider public audience, which accident has, in this instance, afforded to mine. If your favour, Sir, have, as I fear, given them more prominence than they deserve, I can only hope that, by stimulating thought, or, still better, by suggesting experiment, they may pay for the time and space thay have occupied.

To your able correspondents, whose courteous indications have afforded me much light, I beg, in conclusion, to offer my best acknowledgements, and I remain, etc.,

F. O. WARD.

North Wales, July 20th, 1867.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Tungsten, properties and compounds of (O=8).—E. Zettnor. The best method of preparing pure compounds of tungsten, from the mineral, is to fuse the latter with $\frac{1}{3}$ of its weight of sodic carbonate. The fused mass is extracted with boiling water, which, on evaporation, yields crystals of the neutral sodic tungstate, $NaO,WO_3 + 2$ aq. The mother-liquor, acidulated with nitric acid and evaporated, gives crystals of the acid salt, $NaO, 7WO_3 + 16$ aq.

The quantitative determination of tungstic acid may be effected by adding a standard solution of plumbic acetate to an aqueous solution of tungstic acid, acidulated with acetic acid. The results are very accurate.

The atomic weight of tungsten has been deduced from the composition of ferrous and argentic tungstate; the first gave the number 92·038, the latter 91·927. Mean=91 976 or 92.

Metallic tungsten is obtained as a dark grey powder, by melting tungstic acid together with sodium, under a cover of sodic chloride, or by passing a strong electric current through fused sodic tungstate.—(*Pogg. Ann.* cxxx. 16.)

Lead-Chamber Process.—R. Weber. Sulphurous acid, in presence of much water, reduces binoxide of nitrogen to oxide of nitrogen. Sulphuric acid, of a certain strength, prevents this reaction. This explains the loss of nitric acid in the manufacture of sulphuric acid, which always takes place when the sulphuric acid in the lead chamber is below the normal strength.—(*Pogg. Ann.* cxxx. 277.)

Fluorides of Antimony and Arsenic.—Marignac.

Fluoride of antimony forms an amorphous, gum-like mass, when evaporated in vacuo. Its concentrated solution cannot be heated without decomposition. If potassic or sodic hydrate, or ammonia, be added to a very concentrated solution of the fluoride, double fluorides in crystals may be obtained. They are nearly all deliquescent, and their solution is not immediately precipitated by sulphuretted hydrogen, acids, or alkalies. They are stable in the crystalline state, but decompose in solution, forming oxy-fluorides.

The corresponding fluo-arseniates are still more difficult to obtain in crystals. Sulphuretted hydrogen decomposes their solution slowly.—(*Arch. Science*, 1867.)

Dissociation.—H. Debray finds that the phenomenon of dissociation may be observed in solid bodies which are formed by direct combination of a volatile and a non-volatile body.

Pure Iceland spar was heated in a tube, which could be exhausted, or filled with any gas by means of a Geisler's mercury air-pump. At 350°C. the decomposition of the mineral was zero; at 440° scarcely preceptible, at 860° very distinct, but ceased when the pressure in the tube amounted to 85 mm. Heated to 1070° the pressure became stationary at 520 mm. This "tension of dissociation" is constant at a given temperature, increases with the rise of temperature, and is independent of the extent of decomposition the carbonate has undergone. If in these experiments the apparatus, after having been heated, is allowed to cool, the generated carbonic acid is entirely reabsorbed, and a vacuum again produced. The author further finds that caustic lime, at ordinary temperatures, does not obsorb a trace of carbonic acid, if the latter be perfectly dry; the absorption begins at a dark red-heat.—(*Comptes R.* lxiv. 603.)

Hydriodic Acid, action of heat on.—T. Hautefeuille. Hydriodic acid, if gradually heated, begins to decompose at 180°C, the violet colour of the gas increasing slowly up to 440°; but from 440° to 700° the decomposition proceeds rapidly. The amount of decomposed gas varies with the extent of surface. At a given temperature it is greatly increased by spongy platinum, but the latter also causes hydrogen and iodine to combine. If, at a certain temperature, equal volumes of H and I pass over platinum in the finely divided state, the quantity of the gases remaining uncombined is exactly equal to that which would be formed by decomposition, if hydriodic acid had been used.—(*Comptes R.* lxiv. 608.)

Ethers of the Acids of Arsenic (C=12).—T. M. Crafts. The reaction of silicic ethide on boric acid, studied by Friedel and Crafts, in which ethylic borate is formed, has been tried by the latter chemist with the acids of arsenic, but only arsenious acid behaves like boric acid. The action of dry arsenic acid upon silicic ethide takes place under pressure at 220°—230°C., silicic acid is precipitated, and a gas escapes which seems to be ethylene. On distillation, arsenious ethide is obtained. The residue consists of arsenious acid, silicic acid, and some arsenic acid.

Arsenic ethide, $3\ (C_2H_5)\ AsO_4$, is formed by heating ethylic iodide, diluted with twice its volume of ordinary ether, and argentic arseniate, slightly in excess, together in sealed tubes to 120°C. The contents of the tube are extracted with ether, the ether evaporated in a current of carbonic acid, and the remaining liquid distilled under diminished pressure. Under ordinary pressure, arsenic ethide boils at 235°—238°, but decomposes partially. Its sp. gr. at 0°C. is =1·3264. It mixes with water in every proportion, showing then all the reactions of arsenic acid.

Arsenious ethide $3(C_2H_5)AsO_3$, is produced on heating silicic ethide with arsenious acid to 220° under pressure. It boils at 166°—168°. Its vapour density was found ranging from 7·197 to 7·615, according to the temperature at which it was taken; theory requires 7·267. Its sp gr. at 0°C., is =1·224. Water decomposes it.

The ether may also be obtained from argentic arsenite with ethylic iodide.—(*Comptes R.* lxiv. 700.)

Aromatic Hydrocarbons converted into Phenols (C=12).—A. Wurtz. Sulphobenzolic acid and its analogues, melted with potassic hydrate (250°—300°C.), splits up into sulphurous acid and the respective phenol. The phenols thus obtained are very pure. The reaction takes places according to the following equation:

$$SO_2\left\{\begin{matrix}C_6H_5\\OK\end{matrix}\right. + KHO = SO_2\left\{\begin{matrix}K\\OK\end{matrix}\right. + C_6H_5OH.$$

—*Comptes R.* lxiv. 749.

Crystallisable Sugar in Helianthus Tuberosus.—Dubrunfaut. The juice of the tubers of the Jerusalem artichoke, if gathered in September, contain inulin in large quantities; if reaped in March or April, it is found to contain dextrose and a non-crystallisable, inactive sugar instead. These two saccharine matters are, no doubt, produced by the conversion of the inulin, which is formed during the first period of vegetation.—*Comptes R.* lxiv. 764.)

Phenol, derivatives of.—H. Brunk has prepared a series of substitution-compounds of phenol, especially those containing nitryl and bromine together. Their salts crystallise well. He also describes the methylic ethers of the two isomeric nitrophenols, which he finds to be identical with mononitranisol and isonitranisol. The first is an oily liquid, the latter a crystallisable body. Both exchange their nitryl for amide on reduction with tin and chlorhydric acid. The monamidophenyl-methylic ether (anisidin) is a liquid, the isamidophenol-methylic ether (isanisidin), a solid.—(*Zeitsch. Chem. N. F.* iii. 202.)

Phenol-group, Contributions to the history of.—L. Dussart. ($Ꞓ=12, Θ=16$). Naphthalene, on being heated with sulphuric acid (10 parts of the former to 25 of the latter), is completely converted into sulpho-naphthalic acid, which, on continued heating, changes into disulpho-naphthalic acid. If pure naphthalene has been taken, little sulphurous acid is formed. The salts of disulpho-naphthalic acid are decomposed by fusing potassic hydrate under formation of a new body, the analysis of which led to the formula of the diatomic phenol $Ꞓ_{10}H_8Θ_2$. This body is more soluble in water than in naphthol; it dissolves readily in caustic potash, which solution is instantaneously decomposed on exposure to air.—(*Comptes R.* lxiv. 859.)

Benzoin, derivatives of ($Ꞓ=12, Θ=16$).—M. Zinin. If benzoin is heated with fuming chlorhydric acid to 130°C. under pressure, an oily body is formed, which on cooling solidifies to a crystalline mass. Of this mass about 72 per cent. are soluble in ether or alcohol, and this solution, on evaporation, yields crystals of benzil, and a thick yellow oil, insoluble in water, easily soluble in alcohol and ether. The portion insoluble in ether is a new compound which the author calls lepiden; its composition is $Ꞓ_{28}H_{20}Θ$. It is insoluble in water, readily soluble in benzol. It melts at 175°, and evaporates at 220°. Potassic hydrate, either solid or in alcoholic solution, does not act upon lepiden. Nitric acid and chromic acid convert it into crystalline oxy-lepiden $Ꞓ_{28}H_{20}Θ_2$, which is insoluble in water, nearly so in ether, readily soluble in benzol. Its melting point is 220°. Zinc and acetic acid reduce it again to lepiden. A bromine substitution compound of lepiden, $Ꞓ_{28}H_{18}Br_2Θ$, has been obtained by adding bromine to its solution in acetic acid.—(*Acad. Petersb.* xi. 151.)

Platinic and Auric Chlorides, Combinations of.—Weber. (O=8.) The yellow crystals which are obtained on adding fuming nitric acid to a solution of platinic chloride have the composition $PtCl + NO_2Cl + HO$. They dissolve in water with disengagement of NO_2. From a solution of platinic chloride in chlorhydric acid (free from nitric), red brown crystals separate on evaporation under the desiccator, which have the composition of Marignac's double chloride of platinum and sodium, but containing H in place of Na.,—$PtCl_2 + ClH + 6HO$. A similar compound has been obtained with auric chloride $AuCl_3 + HCl + 6HO$.—(*Acad. Berl.*, Feb., 1867.)

Action of Chloride of Sulphur on Metals and Sulphides.—(S=16).—E. Baudrimont has studied the action of sulphurous chloride (S_2Cl) on various metals and sulphides. The reaction in which metallic chloride is formed, and sulphur precipitated, takes place most readily with those metals, the chlorides of which are volatile, but is prevented altogether in the case of magnesium and sodium.—(*Comptes R.* lxiv. 368.)

Benzylic bromide, and bromtoluol.—F. Beilstein. The action of bromine on toluol is analogous to that of chlorine on toluol. Benzylic bromide (not free from bromtoluol) is obtained when vapours of bromine are made to act upon boiling toluol, and bromtoluol (free from benzylic bromide), when bromine in presence of sodium acts on toluol, either cold or hot.—(*Zeitschr. Chem.* N.F., iii. 281.)

Phenylene brown.—Caro and Griess (Θ=12). Experiments of Hofmann, Martius, and Holle, have shown that *β* phenylene-diamine on being acted upon by nitrous acid is decomposed with formation of a brown substance, which under favourable conditions may be obtained as a crystalline body of basic nature. If to a cold, dilute, neutral solution of phenylene-diaminic chlorhydrate is added a neutral solution of a nitrite, a crystalline dark-red mass is precipitated. Washed with water and treated with strong chlorhydric acid, it first dissolves and then the chlorhydrate of the new base separates as a tarry liquor. The latter decomposed in aqueous solution by ammonia, yields the dye in a crystalline state. The phenylene-brown consists chiefly of a new base of the composition $\Theta_{12}H_{13}N_5$, and is derived from *β* phenylene-diamine according to the equation:

$$2\Theta_6H_8N_2 + NH\Theta_2 = \Theta_{12}H_{13}N_5 + 2H_2\Theta.$$

Its constitution is considered to be $\Theta_{12}H_7(NH_2)_3N_2$, that is, triamidoazobenzol.—(*Zeistchr. Chem.* N.F., iii. 278.)

Crystalline Chromic Oxide.—R. Otto has obtained chromic oxide in the crystalline state, by passing a current of hydrogen over potassic bichromate. The salt is reduced to potassic chromate, which serves as the medium in which the oxide crystallises.—(*Ann. Chem. Pharm.*, cxlii. 102.)

Ethyl-pyrophosphoric Acid.—G. Dilling (C=6,O=8). Phosphoric anhydride at ordinary temperature does not act upon zincic ethide; heated together in sealed tubes to 140°C. zincic ethyl-pyrophosphate is formed, besides other products. The basic salt of this acid has the composition,

$$2BaO\left\{\begin{matrix}C_4H_5\\C_4H_5\end{matrix}\right\}P_2O_6,\ O_2$$

Ethyl-pyrophosphoric acid may be considered as a derivative of pyrophosphoric acid in which one or two atoms of oxygen are replaced by ethyl.—(*Zeitschr. Chem.*, N.F. iii. 266.)

Creosote.—E. Probst, in a preliminary communication, states that he has obtained pyrocatechin from beech-wood-creosote by melting the latter with an excess of potassic hydrate. He reserves to himself a more complete investigation of this subject.—(*Zeitschr. Chem.*, N.F. iii. 280.)

Gallic, Pyrogallic, and Oxyphenic Acids, Bromo-derivatives of.—H. Hlasiwetz (Θ=12,Θ=16). These three acids combine readily with bromine, forming the following substitution-compounds:—Bromogallic acid, $\Theta_7H_4Br_2\Theta_5$, readily soluble in hot water, in which solution ferric chloride produces a brilliant violet, ammonia a red coloration. Bromopyrogallic acid, $\Theta_6H_3Br_3\Theta_3$, is somewhat less soluble in water, but gives the same reactions as the former. Bromoxyphenic acid, $\Theta_6H_2Br_4\Theta_2$, is insoluble in water, readily soluble in dilute alcohol; its solution assumes a dark blue colour on addition of ferric chloride.—(*Acad. Wien.*, 55, 1867.)

Titanic Iodide.—P. Hautefeuille. This compound is readily obtained by acting upon titanic chloride with hydriodic acid. When purified by repeated sublimation in a current of hydrogen it forms a brittle red-brown mass, which fuses at 150°C., and crystallises on cooling. It boils above 360°, and its vapour density, taken at 440°, was found =18·054; calculated for 2 volumes, it should be 19·334. It is soluble in water, but the solution soon decomposes with precipitation of titanic acid.—(*Bull. Soc. Chim.*, vii. 201.)

Chloric Acid, determination of.—C. Stelling (O=8). Potassic chlorate is reduced to chloride on being treated with ferrous oxide, according to the equation, $KO,ClO_5 + 12FeO = KCl + 6Fe_2O_3$. This suggested the following method for the determination of chloric acid:—To a solution of the chlorate is added ferrous sulphate and an excess of potassic hydrate; the mixture is boiled and filtered, and in the filtrate the chlorine determined in the usual manner.—(*Zeitschr. Analyt. Chem.*, vi. 32.)

Cobalt and Nickel, Atomic Weights of.—Cl. Winkler has determined the atomic weight of these metals according to the following method:—The metals were prepared in a state of perfect purity; the cobalt by reduction of repeatedly recrystallised purpureo-cobaltic chloride in a current of hydrogen at a high temperature. The nickel by adding to a solution of the commercial carbonate in chlorhydric acid sodic hypochlorite, and treating the liquid in this manner again so long as any cobalt could be detected in it; the solution was then purified from traces of copper and arsenic and precipitated with sodic carbonate. The carbonate was converted into chloride, and sublimed in a current of chlorine, and lastly reduced in a current of hydrogen.

Weighed quantities of the metals were then immersed in a perfectly neutral, concentrated, cold solution of sodio-auric chloride, and the weight of the precipitated gold determined. The mean of five experiments with cobalt gave the number 29·496. The mean of four with nickel, the number 29·527.

The atomic weights of these metals may therefore be taken as identical, *i.e.*, 29·5.—(*Zeit. Analyt. Ch.*, vi. 18.)

Succinic Acid, constitution of.—H. Wichelhaus (Θ=12,Θ=16). While succinic acid, in accordance with its formation from bicyanethylene, has generally been viewed as bicarbethylenic acid,

$$\begin{array}{l}\Theta H_2.\Theta\Theta.\Theta H\\ |\\ \Theta H_2.\Theta\Theta.\Theta H\end{array}$$

it has been represented recently by Claus (*Ann. Ch. Pharm.* cxli., 49) as bicarbethylidenic acid,

$$\begin{array}{l}\Theta H_3\\ |\\ \Theta H(\Theta\Theta.\Theta H)_2\end{array}$$

As a necessary support to the latter view, the acid derived by H. Müller from cyanpropionic acid (which was prepared from chlorpropionic ethide) should have been identical with succinic acid. This, however, is not the case; they differ in melting point, solubility, and in their behaviour towards ferric chloride. On the other hand, an acid has been obtained from *β* chlorpropionic acid (derived from glyceric acid) by the same reaction, that is, treatment with potassic cyanide and decomposition with potassic hydrate, which has the same properties as succinic acid. It would appear, therefore, that *β* chlorpropionic acid is the starting point for the synthesis of succinic acid, and that the latter must still be considered as bicarbethylenic acid.—(*Zeitschr. Chem.*, N.F. iii., 247.)

Tannic Acid.—H. Hlasiwetz (Θ=12, Θ=16). Caffetannic acid, when treated with potassic hydrate, is successively converted into Caffeic acid, sugar, and protocatechuic acid. Caffeic acid

$$\Theta_9H_8\Theta_4\ \tfrac{1}{2}H_2\Theta$$

is obtained by boiling caffetannic acid with a solution of potassic hydrate of 1.25, sp. gr. ¾ of an hour. It is then precipitated with sulphuric acid, recrystallised from water, and decolorised with animal charcoal. It is soluble in alcohol; ferric chloride produces in its aqueous solution a green colour, which turns dark red on addition of soda; it is precipitated by plumbic acetate, and converted into oxalic acid by nitric acid. Fused with potassic hydrate, it breaks up into protocatechuic and acetic acid, and dry distillation converts it into pyrocatechin. Treated with sodium amalgam it takes up 2H forming hydrocaffeic acid. Caffeic acid is triatomic, and is the third in the following series:

Cinnamic acid.....$=\text{Ꞓ}_9H_7\Theta.\Theta H$
Coumaric acid.....$=\text{Ꞓ}_9H_6\Theta 2\Theta H$
Caffeic acid.......$=\text{Ꞓ}_9H_5\Theta 3\Theta H$

which, on being treated with fusing potassic hydrate, are converted, with formation of acetic acid, into the series:

Benzoic acid.......$=\text{Ꞓ}_7H_5\Theta.\Theta H$
Salycylic acid......$=\text{Ꞓ}_7H_4\Theta.2\Theta H$
Protocatechuic acid $=\text{Ꞓ}_7H_3\Theta.3\Theta H$

The solution from which the caffeic acid has crystallized contains sugar; it is neutralised with potassic hydrate, evaporated and extracted with alcohol. After purification the sugar appears as a syrupy, non-crystallisable mass, showing the usual reactions. An analysis gave the formula, $\text{Ꞓ}_6H_{10}\Theta_4$.

Caffetannic acid, by its splitting up into caffeic acid and sugar, is thus proved to be a glucosid.—(*Akad. Wein.* lv. 1867.

Ammoniacal Platinum Compounds.—T. F. Cleve has given an account of his researches on the platinum-bases, comprising a critical examination fo those already known, and a description of many new derivatives of these interesting compounds. For detail, we must refer to the original paper.—(*Bull. Soc. Chim.* vii. 12; or, more complete, *Acta Societ. Scient. d' Uphala*, 1866.)

Tea, constituents of.—H. Hlasiwetz and Malin. ($\text{Ꞓ}=12, \Theta=16$). Rochleder states that tannic acid and boheic acid may be obtained from a decoction of tea by precipitation, first with neutral plumbic acetate, and the filtrate therefrom with basic or ammoniacal plumbic acetate. The authors, however, find that both precipitates alike contain tannic, gallic, and oxalic acid; the latter, besides, a small quantity of quercetin,

$$\text{Ꞓ}_{27}H_{18}\Theta_{12},$$

which imparts to it a yellow colour. If the lead precipitate is decomposed with sulphuretted hydrogen, and the filtrate boiled with dilute sulphuric acid, much more of this body is obtained; from which it appears that the original solution does not contain quercetin in the free state, but probably as quercitrin.—(*Akad. Wien.* lv., 1867.)

Aromatic Aldehydes under the Influence of Dehydrating agents.—V. Longuinine. ($\text{Ꞓ}=12$, $\Theta=16$.) Cuminol ($\text{Ꞓ}_{10}H_{12}\Theta$.) is powerfully acted upon by phosphoric anhydride, being converted by it into a resinous mass. Zincic chloride is without action in the cold, and almost so at the temperature of the water-bath, but if employed in the fused state, a violent reaction takes place, which results in the formation of Cymol ($\text{Ꞓ}_{12}H_{14}$). The author believes that first the hydrocarbon $\text{Ꞓ}_{10}H_{10}$ is formed, which subsequently combines with hydrogen, resulting from the complete decomposition of a portion of the aldehyde.—(*Comptes R.* lxiv. 785.)

Argentic Iodide.—H. Fizeau finds that amorphous argentic iodide (prepared by precipitation), like the crystallised and fused modification (Chemical News, No. 386), shows the remarkable phenomenon of contraction with rising, and expansion with falling temperature.—(*Comptes R.* lxiv. 772.)

Iodine-starch.—H. Pellet. From experiments made as to the cause of the decolorisation of iodine-starch on heating, and reappearance of the colour on cooling, the author arrives at the following conclusions:—1, Decolorisation is caused by the solution of iodine-starch in an excess of hot starch; the solubility being less in the cold, the colour reappears again on cooling. 2. Iodine-starch is decomposed at 100°C. and iodine volatilises. 3. Iodine-starch remains unchanged in alcohol, being equally insoluble in that liquor whether hot or cold. 4. Iodine-starch may be regarded as a salt, which in certain solvents is more readily soluble when hot, than when they are cold.—(*Bull. Soc. Chim.* vii. 147.)

Ozonometry.—A. Cossa is engaged with experiments, the object of which is to discover an exact method for the determination of ozone in atmospheric air. The author has at present established the following facts:—1. A solution of pure potassic hydrate (free from every trace of organic matter) absorbs nitro-oxygen compounds without destroying ozone. 2. The quantity of iodine liberated in a solution of pure potassic iodide is in exact proportion to the amount of ozone that has passed through the liquid, and may be accurately measured by means of Bunsen's volumetric liquid. —(*Zeit. Analyt. Ch.* vi. 24.)

Quinine, Testing of.—Stoddart recommends the following methods for testing quinine for quinidine, etc.:—6 grammes of the suspected quinine are dissolved in a test tube in 5 grammes sulphuric acid, diluted with 3 grammes water; to this is added 7·5 grammes ether, 18 grammes alcohol, and 2 grammes of a solution of sodic hydrate containing about 8 per cent. The mixture is well shaken and left to itself for 12 hours. If quinidine, cinchonine, or cinchonidine are present, they will be found in a layer below the ether—quinidine as an oily liquid, cinchonidine in crystals.

The second method consists of a microscopic examination of the crystalline precipitate produced in a saturated and neutral solution of quininic sulphate by potassic sulphocyanide. (10 gr. in 45 gr. water.)—(*Journ. Pharm. Chim.* iv. 50.)

Ferric Chloride, Volatility of.—R. Fresenius. The author has made a few experiments in order to decide whether any loss is likely to occur in analytical operations through iron being volatilised during evaporation of its solution with an excess of chlorhydric acid. In one experiment he evaporated ferric chloride with chlorhydric acid nearly to dryness; in a second, the evaporation was performed in presence of an alkaline chloride, and the mass afterwards kept on the water-bath for twelve hours; in a third, ferric chloride, with much chlorhydric acid, was kept boiling for 1½ hours. In neither case did any loss of iron take place.—(*Zeitschr. Analyt. Chem.* vi. 92.)

Absorption of Carbonic Acid by Oxides.—J. Kolb finds that the anhydrous and monohydrated oxides of potassium, sodium, magnesium, and barium, like calcic oxide, do not increase in weight when exposed to dry carbonic anhydride, but absorption takes place if the latter is charged with moisture.—(*Comptes R.* lxiv. 861.)

Ozone, Density of.—T. L. Soret. Having previously found that the density of ozone is 1½ times as great as oxygen, the author now applies the method of diffusion as a control of his former observations.

Under similar conditions, in one case, a known mixture of chlorine and oxygen, in another a known mixture of ozone and oxygen, were diffused into pure oxygen. The velocity with which chlorine and ozone passed through the diaphragm was in the ratio:—

$$\frac{\text{Chlorine}\ldots\ldots227}{\text{Ozone}\ldots\ldots\ldots271}=\cdot 8382$$

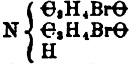
This value approaches closely that of the inversed proportions of the square-roots of their respective densities, taking that of ozone as 1½ that of oxygen, *i.e.* $=\cdot 8243$.—(*Comptes. R.* lxiv. 904.)

Pseudo-hexylurea.—T. T. Chydenius. This compound is prepared by heating pseudo-hexylic iodide (obtained from mannite) with argentic cyanate to 50°—60°C. The reaction is violent, and a liquid strongly affecting the eyes, and possessing a very disagreeable odour, distils over. An excess of ammonia is added, and the solid mass, thus formed, recrystallised from water. Pseudo-hexylurea crystallises in white needles which are readily soluble in hot water, ether, and alcohol, melt at 127°C., and boil, with partial decomposition, at 220°. Its formula is:

$$N_2\left\{\begin{array}{l}\text{Ꞓ}\Theta\\(\text{Ꞓ}_6H_{12}H,)H\\H_2\end{array}\right.$$

When heated with a strong aqueous solution of potassic hydrate in sealed tubes, decomposition sets in at 230°—250°, ammonia being given off, and an oily liquid formed, which probably is isopropylamine.—(*Comptes. R.* lxiv. 975.)

Nitriles, Action on Bromine of.—C. Engler. Propionitrile and bromine combine when heated together, forming bromhydrate of propionitrile, $N\text{Ꞓ}_3H_4Br_2HBr_2$. The body is very deliquescent, fuses at 64°C., and begins to sublime, with partial decomposition, at 72°. It will be seen that bromine in this case acts differently from chlorine, the latter producing, as is well known, dichlorpropionitrile. $N\text{Ꞓ}_3H_3Cl_2$. Water decomposes the bromhydrate to bromammonium, bromhydric acid, and a new body which is dimonobrompropionamid.



$$N\begin{cases}\text{Ꞓ}_3H_4Br\Theta\\ \text{Ꞓ}_3H_4Br\Theta\\ H\end{cases}$$

This latter compound is obtained in white crystals which are soluble in alcohol and ether, almost insoluble in cold water, fuse at 148°C., and decompose at 152°. Aqueous potassic hydrate decomposes the amide with formation of a new acid, the argentic salt of which has the composition $\text{Ꞓ}_3H_5Ag\Theta_3$. Dimonobrombutyramide, $N(\text{Ꞓ}_4H_6Br\Theta)_2H$, is prepared in the same way as the propyle-compound, which it resembles closely.—(*Ann. Chem. Pharm.* cxlii. 65.)

Trichlorhydrin, Action of Ammonia on.—C. Engler. Dimonochlorallylamine

$$N\begin{cases}\text{Ꞓ}_3H_4Cl\\ \text{Ꞓ}_3H_4Cl\\ H\end{cases}$$

is formed by digesting trichlorhydrin with alcoholic ammonia under pressure at 130°—140°C. It is a heavy oil, sparingly soluble in water, soluble in alcohol and ether; it decomposes partially on distillation, the portion analysed went over between 185° and 195°. The salts of this base are deliquescent, and difficult to obtain in crystals from an aqueous solution. The platino-chloride is readily soluble in water, moderately so in alcohol, and nearly insoluble in ether. It has the composition $N(\text{Ꞓ}_3H_4Cl)2H_2Cl,PtCl_2$.

An ethyl-substitution-compound of dimonochlorallylamine is obtained by heating the latter with ethylic iodide in sealed tubes to 100°C. Its composition is

$$N\begin{cases}\text{Ꞓ}_3H_4Cl\\ \text{Ꞓ}_3H_4Cl\\ \text{Ꞓ}_2H_5\end{cases}$$

It differs but little from the original compound.—(*Ann. Chem. Pharm.* cxii. 77.)

Analysis of Organic Compounds, New Method of.—A. Mitscherlich. Of this new method of analysis, which is applicable to all organic, and many inorganic compounds, and which includes the direct determination of oxygen, we can only indicate the principle, as it would be impossible in these few lines to give, without pictorial illustrations, an intelligible description of the complicated apparatus and manipulations required.

1. Oxygen and hydrogen are determined together by heating the substance in a current of chlorine, passing the products of combustion over red-hot charcoal, and absorbing the chlorhydric acid, carbonic anhydride, and carbonic oxide formed by a saturated solution of plumbic nitrate, a solution of potassic hydrate, and a solution of cuprous chloride in chlorhydric acid respectively.

2. Chlorine, bromine, iodine, and sulphur are determined simultaneously with carbon and nitrogen, by volatilising the substance in a current of hydrogen, burning the mixed gases and vapours with oxygen, removing the water by means of sulphuric acid, and collecting the products of combustion in weighed vessels—with the exception of nitrogen, which is measured. The products of combustion, besides the water, may consist of carbonic anhydride, chlorhydric acid, bromine, iodine, sulphurous acid, sulphuric acid, and traces of brom- and chlorhydric acid. A residue of carbon may also be left in the combustion tube. The water is absorbed by sulphuric acid, the chlorhydric acid by plumbic nitrate, bromine by mercuric oxide, iodine is weighed as such, sulphurous acid is absorbed by potassic bichromate, carbonic anhydride by potassic hydrate, nitrogen is measured, and the residual carbon weighed.

The specimens of analysis given, prove that very accurate results may be obtained by this new method.—(*Pogg. Ann.* cxxx. 536.)

Qualitative Analysis without using Sulphuretted Hydrogen and Ammonic Sulphide.—E. Zettnow. The author tests an aqueous solution, which may contain all of the more common bases, with the following reagents in succession:—

1. Chlorhydric acid precipitates lead, mercury, and silver.
2. Sulphuric acid precipitates lead, barium, strontium, and calcium.
3. Baric hydrate sets free ammonia, the filtrate is used for the detection of sodium and potassium.
4. Zinc is added to the filtrate from 2, the hydrogen ignited and tested for antimony and arsenic; antimony, arsenic, tin, mercury, copper, cadmium, and bismuth are precipitated.
5. Baric carbonate precipitates from the filtrate from 4, iron, chromium, and aluminium.
6. Ammonic carbonate, after removal of the baryta, precipitates from the filtrate of 5, manganese and calcium; the filtrate is tested for magnesium, cobalt, and nickel.
7. Zinc is tested for in the original solution.—(*Pogg. Ann.* cxxx. 324.)

Reagent for Nitric Acid.—C. D. Braun. A very delicate test for nitric acid is, according to C. D. Braun, anilinic sulphate. Half a c.c. of a solution of the aniline-salt is added to one c.c. of pure, strong sulphuric acid, contained in a watch-glass. A glass rod is then moistened with the liquid to be tested, and moved about in the aniline mixture, when a red coloration indicates the presence of nitric acid.—(*Zeit. Analyt. Ch.* vi. 71.)

MISCELLANEOUS.

The Representation of the University of London.—We have been requested to state that amongst the names of those who have been proposed to represent this University in Parliament that of Sir John Lubbock, Bart., F.R.S., has met with many warm advocates. There is no doubt that Sir John Lubbock possesses unusual qualifications for such a task; for, while his intellectual and scientific eminence would give weight to his words on questions of science, of education, and civil polity, his position in the City of London, and his reputation as a man of business, would obtain for him a hearing that might be denied to a man occupied exclusively in scientific pursuits. For the same reason he is peculiarly fitted to be the spokesman in the House of Commons of the large and increasing body of scientific men—a class whose opinions have hitherto found very inadequate expression in Parliament. We have heard the name of Dr. W. Allen Miller, F.R.S., proposed as that of a gentleman also fitted to represent this University, and should Dr. Miller be induced to come forward as a candidate, there is little doubt that he will obtain the unanimous support of the chemical fraternity; but in the event of this rumour turning out incorrect, chemists could not have a better representative than Sir John Lubbock, supported as he is by such well known men as Dr. A. Crum Brown, G. C. Foster, Dr. Odling, Dr. Pye-Smith, and H. Watts.

Suspension of the Storm Warnings.—We have more than once expressed our regret that the scientific committee, which has been appointed by the President and Council of the Royal Society, has advised the discontinuance of the Storm Warnings of the late Admiral Fitzroy. At the last meeting of the Literary and Philosophical Society, of Manchester, the subject was again brought forward by Mr. Baxendell, who strongly urged that the Board of Trade would again take the management of the Meteorological Department into their own hands, and appoint Mr. Babington, or some other competent and responsible person, to resume and carry on the system of storm warnings. As an illustration of the lamentable consequences of the suspension of storm signals, it may be stated that among the wrecks caused by the unusually heavy gale of the 10th of April, there were four vessels, which had sailed from Liverpool just before the commencement of the storm. Three of these vessels had been thrown on the Lancashire coast, and totally lost, and the lives of three of the crew of one vessel had been sacrificed. The fourth vessel had foundered in the Irish Sea, and all hands were lost. Now the meteorological phenomena immediately preceding the occurrence of this storm were of such a nature that there could have been no difficulty in giving notice of its approach in ample time to prevent the sailing of these vessels. In fact, without the aid of telegrams from distant stations, its approach was confidently announced in Manchester, so early as the evening of Monday, the 8th of April, and the direction in which the wind would blow during the most violent period of the storm was also stated at the same time.

The Paris Exhibition.—Mr. Sterry Hunt, F.R.S., the celebrated Canadian Geologist, has been made an officer of the Legion of Honour. Had its acceptance been permitted by our Government, a number of honours would have been conferred, on Monday last, upon many English men of science.

The Human Voice.—Dion Bourcicault, commenting on the Albert Hall of Science and Art, in the *Pall Mall Gazette*, says:—"The human voice, when speaking with clear articulation and supplied from good lungs, will fill 400,000 cubic feet of air, provided they be enclosed in a proper manner, and the voice placed and directed advantageously. The same voice singing can fill, with equal facility, 600,000 cubic feet. When singing, the vowels are principally used, because it is necessary to dwell upon a note, and we cannot prolong a consonant. In speaking, on the contrary, we depend for articulation on the consonants; but their short percussive sound does not travel. When we shout, or in open-air speaking, which partakes of shouting, we prolong the vowels, drawling the syllable of each word; but what we gain in sound we lose in clearness of articulation; expression is lost in monotony, because its fineness depends on the infinite variety of which the consonant is capable and bestows on the vowel. 2000 voices, singing or speaking together, travel no further than one voice. They may fill a certain area more completely with that intricacy of waves which, when very troublesome, we call a din; but each voice exerts its own influence on the air, according to its power, and dies away within certain limits. A second voice acts independently, and produces its own separate effect, not fortifying the first, but distinct from it. And so with any number of voices—say 10,000—shouting together, if a single trumpeter were placed among them, the note of his trumpet would be heard clearly at a distance where the Babel of voices would have expired in a murmur. Yet, among the din produced by the 10,000 voices, the trumpet would be inaudible. To illustrate this theory more clearly, it is plain that 2000 persons cannot throw stones further than one person. It is true that the air, within certain limits, will be more full of stones; but they will all come to the ground within a limited area.

On the Manufacture of Zinc.—C. Trainer. Comparison of the Belgian and Silesian distilling furnaces gives the following result: The Belgian furnaces with some 60 effective retorts in 7 to 8 horizontal rows require less fuel, the process is more intense, is finished sooner, and yields more. However, they require a full-flaming coal, and the consumption of retorts is greater; and when breakages occur the under retorts often suffer. The attention to these furnaces requires very intelligent and experienced workmen, as they have to keep up an equal temperature of all the retorts, above and below, front and back. On the other hand, the Silesian furnaces require less skilful workmen, and less vessels, as they last longer, while the consumption of fuel is larger, but a less open burning coal may be used. The latest improvements in the Silesian furnaces for the purpose of saving fuel (two rows of muffles above each other, and a downward flame) require a free burning coal as well as more expert workmen. A greater durability is ascribed to the Silesian furnaces than to the Belgian; this advantage, however, is doubtful after having introduced considerably improved arrangements in the front wall of the Belgian furnaces. Such improved furnaces lasted two years, at an average, near Iserlohn. It is advantageous to the durability of the furnaces for them always to be attended by the same workmen. The Silesian process extracts more zinc from the ores on account of their longer stay in the furnace and the less amount of breakage of the distilling vessels, whilst the Belgian furnaces have, for a fixed time, greater productiveness. When the ore forms tough slags the Silesian method is preferable. Trials of zinc-melting in blast-furnaces have not been successful. It would lead to considerable advantage if the distillation of the zinc-ore could be effected in a large flat muffle, which could be sufficiently heated and would not crack. Such an apparatus, on the one side with openings for charging, on the other with vessels for condensation, would require a less amount of fuel.—*Berg- und Hütten-Zeitung*, 1867, No. 24.

Mercerising Cotton.—To Mr. Mercer must be attributed the discovery of the peculiar action of caustic soda and sulphuric acid upon cotton. This singular process, now called "mercerising," has the effect of untwisting the normally twisted flattened tubes of cotton filaments and converting them into cylindrical tubes. When colours are applied to the cotton so treated, they pass more readily through the minute pores of the tubes and are precipitated in denser layers in the interior of the latter, whereby darker and more permanent shades are produced. Calico so treated becomes greatly increased in strength, and though hitherto no large quantities of cloth thus prepared have been printed, owing to the expense of preparation, advantage has been taken of the process to prepare the cotton fabric used in the production of the endless web known to calico printers as the india rubber blanket, which, when made with prepared calico, is rendered much more durable.—*Proc. Lit. Phil. Soc., Manchester.*

Determination of Bismuth in Lead Alloys.—(Patera). The alloys are dissolved in nitric acid, the solution diluted with water, and the bismuth precipitated by a strip of pure lead. The precipitated bismuth, black of colour and in the state of powder, is quickly washed off the lead, the solution of lead is decanted; the bismuth is then washed first with water and then with alcohol, filtered on a weighed filter, dried and weighed.—*Berggeist*, 1867, No. 28.

Blasting with Sodium.—Experiments are now being made, in the Isle of Man and elsewhere, to ascertain the value of sodium, in contact with water and other substances, for blasting purposes.—*British Journal of Photography.*

An Old Anæsthetic Revived.—An enterprising American dentist advertises that he now takes teeth out painlessly by merely causing the patient to inhale the *constituents of the atmosphere—oxygen and hydrogen—chemically combined.*

Partzite.—This mineral, discovered by Dr. Part in 1865, has been investigated by Albert Arents. It occurs in amorphous masses, generally without lustre. Fracture, varies from conchoidal to even; colour, yellowish green to blackish green and black; sp. gr. = 3·8; hardness, 3·4. Before the blowpipe on platinum it is melted, but with difficulty, to a black slag; on charcoal, especially with addition of carbonate of soda and powdered charcoal, a metallic button is easily obtained much resembling pure antimony. Sulphuric, nitric, or hydrochloric acid decomposes the mineral. An analysis gave numbers corresponding to the formula:

$$(\mathrm{CuO, AgO, PbO, FeO})_3\mathrm{SbO}_5 + 3\mathrm{HO}$$

Partzite occurs with argentiferous galena.—*Silliman's Journal*, May, 1867.

Action of Water upon Carbohydrates at an Elevated Temperature.—O. Loew. Cane sugar at 160°C. yields levolosan and glucose; at 180° caramelan; at 200° caramel, assamar, and carmelin; and at about 250° is totally decomposed. The author finds that the presence of water makes a great difference. Sugar is perfectly decomposed when heated with water in a sealed tube to 160°, the water seeming to act as an acid. Sugar heated with alcohol in a sealed tube to the same temperature remains unaltered. Sugar heated with baryta water in tubes is not decomposed at 170°C. Water acts in the same way upon other "carbohydrates." Starch, gum, and milk sugar with water are decomposed by five hours' heating at 70°C. The products are formic acid, carbon, and carbonic acid.—*Silliman's Journal*, May, 1867.

A Catastrophe Averted.—In the course of last winter the river Irwell rose nearly twenty feet above its ordinary level, and flooded the works of the Magnesium Metal Company on the Salford side to a depth of about seven feet in every part. There were then from three to four hundred-weight of sodium in stock, and, soon after the commencement of the flood, the room in which the sodium was stored was two feet deep in water; but, as it rained in torrents, it was then considered best not to run the risk of attempting to move it off the premises. The sodium was stored in long narrow jars, with loosely-fitting covers, made air-tight by allowing the bottoms of the lids to rest in a circular groove filled with oil. As the flood did not abate, and the position began to grow more dangerous, one of the men volunteered to go on the roof of the sodium shed and watch the water rise, and for hours he lay upon the roof in a soaking shower of rain, watching the sodium jars. Inch by inch the water rose, and at last, when it was only half a foot from the top of the jars, he drew his head out of the hole in the roof where it had been sticking so long and summoned the rest of the men. They unslated the roof of the store room, let themselves down into the water, now reaching nearly to their armpits, and removed the sodium lump by lump into other vessels placed among the rafters of the roof. By accident one little ingot of sodium fell into the water, causing the courage of the men to falter; but the lump fortunately only fumed and fizzed, and dissolved away without exploding. After the flood was over the Magnesium Metal Company built a platform near the roof, on which all sodium is now stored. We have not heard what bonus the Company voted to the men who removed the sodium, especially to the one who stuck to the top of the roof like a limpet to a rock in a storm, but doubtless it was something handsome.—*British Journal of Photography.*

Obituary.—Our readers will probably have already seen the announcement of the death, and have lamented the loss, of Dr. Thomas Richardson. Dr. Richardson was Reader in Chemistry at the University of Durham, as well as a Fellow of the Royal Societies of London and Edinburgh, and member of the Royal Irish Academy. He died somewhat suddenly, at Wigan, on the 10th inst., of congestion of the brain. Of late years Dr. Richardson was best known to the chemical world by his work in connection with "Richardson and Watts' Chemical Technology." Several papers of his are to be found in the volumes of this Journal and the *Chemical Gazette*. They relate chiefly to manufacturing chemistry. Many chemists will have pleasent reminiscences of their visit to the Newcastle meeting of the British Association, and of Dr. Richardson's hospitality on that occasion.

The Water we Drink.—The Registrar-General in his weekly report says, that on the intermittent system of supplying, the pipes are often left empty, and in that case sometimes get saturated with impurities. This happened in Portland-road, where analysis detected sewage contamination in the water drawn from the stand pipe on June 1st; the sewage was equivalent to 1 per cent. of the water, which was turbid when drawn, and, after standing a few days, emitted an offensive odour, and threw down flocculent matter.

University of London.—Science Examination.—Results.—FIRST B. Sc.—1st Division: Bottomley, Carey, Gum, Harding, Hopkinson, Robinson, Tilden, Wormell.

2nd Division: Ball, Brice, Bright, Graham, Leonard, Pearsall, Sheldon, Thorp, Whipple.

SECOND B. Sc.—1st Division: Exall, W. H. (King's College); Payne, J. F. (St. George's Hospital); Smith, R. S. (King's College).

2nd Division: Duer, S. (private study); Ridge, J. J. (St. Thomas' Hospital); Robinson, E. (Owen's College); Sprengell, J. C. F. L. (private study); Waller, A., B.A. (St. Thomas' Hospital); Wigner, J. M. (private study).

HONOURS.—Exall, W. H., second class; Chemistry.

PREL. SCIENT. M.B.—1st Division: Aveling, Ball, Barff, Bruce, Burn, Carter, C. H., Elkington, Gibbings, Harris, J. A., Harris, M., Haynes, Hunt, Saunders, Wall.

2nd Division: Bindley, Burgess, Carr, Carter, A. H., Cotterill, Coupland, Cross, De Mèric, Edwards, Fox, T. C., Franklin, Graham, Herman, Ingoldley, Jones, T., Lowe, Lyell, Male, Paget, Perkins, Pippette, Puglie, Ralli, Rayner, Rowland, Rugg, Simon, Sloman, Smith, Southee, Taunton, Waddy, Willaus, Williams.

Experiments on the Poison of the Cobra-di-capella.—The *Melbourne Argus*, for April 26th, contains an interesting article, by Dr. G. B. Halford, on the above subject, from which we extract the following:—"The melancholy accident which so lately happened with the cobra-di-capella induced me to make some experiments and observations upon the action of the reptile's poison. When a person is mortally bitten by the cobra-di-capella, molecules of living 'germinal' matter are thrown into the blood, and speedily grow into cells, and as rapidly multiply; so that, in a few hours, millions upon millions are produced at the expense, as far as I can at present see, of the oxygen absorbed into the blood during inspiration; hence the gradual decrease and ultimate extinction of combustion and chemical change in every other part of the body, followed by coldness, sleepiness, insensibility, slow breathing, and death. The cells which thus render in so short a time the blood unfit to support life are circular, with a diameter on the average of one seventeen-hundredth of an inch. They contain a nearly round nucleus of one two-thousand-eight-hundredth of an inch in breadth, which, when further magnified, is seen to contain other still more minute spherules of living 'germinal' matter. In addition to this, the application of magenta reveals a minute coloured spot at some part of the circumference of the cell. This, besides its size, distinguishes it from the white pus or lymph corpuscle. Thus, then, it would seem that, as the vegetable cell requires for its growth inorganic food and the liberation of oxygen, so the animal cell requires for its growth organic food and the absorption of oxygen. Its food is present in the blood, and it meets the oxygen in the lungs; thus, the whole blood becomes disorganized, and nothing is found after death but dark fluid blood, the fluidity indicating its loss of fibrine, the dark colour its want of oxygen, which it readily absorbs on exposure after death. It results, then, that a person dies slowly asphyxiated by deprivation of oxygen, in whatever other way the poison may also act, and so far as the ordinary examination of the blood goes, the *post-mortem* appearances are similar to those seen after drowning and suffocation. I have many reasons for believing that the *materies morbi* of cholera is a nearly allied animal poison. I hope also to show the presence of the poison of our snakes in the blood of bitten and inoculated animals, and to make some experiments on the possibility of saving life.

Behaviour of Manganese with Chlorate of Pot-

ash before the Blowpipe.—If chlorate of potash be heated by means of a blowpipe, in a tube closed at one end till oxygen is evolved, and then a trace of manganese added, the potash salt will assume a purple colour, owing to the production of permanganate of potash. This reaction of manganese is quite as delicate as the one proposed by Berzelius. —*T. Landaner.*

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Jungfleish: "*On some Points of Relation between the Melting Points, Densities, and Specific Volumes of some Chlorinated Derivatives of Benzene.*"

NOTES AND QUERIES.

The use of Superheated Steam.—Sir,—About ten years since I carried out a series of experiments with superheated steam, in conjunction with an experienced engineer. In the first instance the steam was applied direct from the boiler at a pressure of 50 lbs., and passed through cast-iron cylinders, heated to redness, from thence through cap welded wrought-iron pipes to a cast-iron steam jacketted pan or pot (each pot was 1½ inches in thickness, and very strongly bolted together). As soon as the superheated steam passed through the pipes, the gun metal steam taps instantly broke off short, owing to the expansion. The stays to the pipes were then removed and the taps replaced. After the superheated steam had been applied to the jacketted pot for upwards of two hours, the interior pot burst from the outer pot at the flange, and was projected through the roof of the building to some considerable distance, and the walls on each side of the building were blown down (the pot weighing about 12 cwt). Some difference of opinion existed as to the cause of the accident, as the steam was not locked in; the valve at the bottom of the pot was open, and also the valve for the outgoing steam. Perhaps the steam, being highly elastic, could not escape with sufficient rapidity. After considerable experience I have employed superheated steam with great success and most economical results both for desiccation and the evaporation of saline solutions, etc. Superheating steam does not require an expensive apparatus; it can be readily accomplished at the back of the furnace of a steam boiler, more especially where Jukes' smoke apparatus is used. A very even temperature can be easily obtained, and in operation it is even superior to Perkins' hot water apparatus, although I have not obtained so high a temperature.—W. H.

Cheap Grease.—Sir,—I am endeavouring to make cheap grease. I have succeeded in making the superior greases. But with the cheapest greases there appears to be a difficulty which I cannot master. They are sold here at 10s. 9s. and 8s. per cwt. These prices are so low that it is to me impracticable to use any other ingredients but rosin, alkali and water. But I find that grease made with these only is sticky and drying, and totally unsaleable. Can any of your subscribers give me an economical recipe for making a good, yet cheap, rosin grease, and greases which will afford a good profit when sold at the above prices?—J. S. W.

To Destroy Ants.—Sir,—Should carbolic acid fail, try liquor ammoniæ fortis: ·880. This is by far the most effective for black beetles.—Q.

Charcoal Biscuits.—Sir,—To make charcoal biscuits, take flour, 1 pound; carbonate of ammonia in fine powder, 1½ drachms; white sugar in fine powder, 2 ounces; mix well together—butter, 2 ounces; one egg; mix into a stiff paste with new milk, and beat well with a rolling pin for 20 minutes; roll out thin and cut out the biscuits with an inverted egg-cup; bake in a quick oven for 15 minutes. Levigated cedar wood charcoal is to be had of Warrick, 3, Garlick Hill, London, and ready made charcoal biscuits of Mr. Bragg, 2, Wigmore Street, Cavendish Square, London.—Subscriber.

Cure for Dry Rot in Houses.—Sir,—I think there is an important oversight in the communication on this subject in your issue of 21st inst. At 27th line should it not read "*beneath* the joists?" I have a remarkable instance in my mind when asphalt had been applied merely *between* the joints of a gentleman's mansion—these joists or sleepers were supported in the centre and nailed to wooden pegs, driven about 18 inches into the soil. In about four years afterwards the whole of the lower apartments were one mass of dry rot, the said pegs having formed excellent conductors. All the woodwork was renewed, and I recommended asphalt to be spread *below, and the sleepers simply to be laid upon the smooth hard surface thus formed.* I believe this has always been effectual. I know a case just now where dry rot has reached the bedrooms.—W. B.

Chemical Calculus.—Sir,—Allow me to point out a correction which it would be desirable to make in your otherwise excellent abstract of my note at the Royal Society on the "Chemical Calculus." In the abstract my translation of Brodie's formula for hydrochloric acid is given thus:—

$$H_2{\genfrac{}{}{0pt}{}{Cl}{H}}$$

instead of thus:—

$$H_2\frac{Cl}{H}$$

And in like manner the lines which I employ between the numerator and denominator of other symbols in the form of division is omitted. My intention was to use the symbol of division to denote decomposition, just as the symbol of multiplication is habitually employed in chemical formulæ to denote combination. I notice that by some accident the number 73 is given as the molecular weight of hydrochloric acid, instead of 36·5.—Alex. W. Williamson.

Acids from Palm Oils.—Sir,—I wish to know the quantities of hard, white palmitic acid and liquid oleic acid which are usually procured from one ton of average palm oil by saponification, followed by distillation and cold and hot pressure. 2ndly. What proportions of the fatty acids are procured from tallow by the lime process, as adopted generally on the continent. I find sundry loose statements in various technical publications, but as they differ so widely I am anxious to learn from some practical person what are the real results obtained in actual working.—Delta.

Refrigerating Machine.—Sir,—Is there any manageable machine in use for manufacturing purposes, for cooling mother liquors?—P.

Distilling Oil.—Sir,—Can any of your readers inform me of any work that treats of oil distilling? I can find no information in any work on chemistry. I want information on rosin oil distilling and refining, and the improvements made in this branch of business. What is the best process for refining rosin oil, nearly destitute of smell, and of a blueish colour?—H. J.

Cheap Grease.—Your correspondent, J. S. W., should try a grease made from the last oil or grease obtained during the distillation of coal tar, or he could try a mixture of rosin and the grease referred to. If your correspondent added a small quantity of the commonest soap to the grease, he would find a great improvement. This would make the cheapest grease for colliery and other purposes.—H.

Charcoal Biscuits.—Sir,—To the receipt given last week add two ounces of levigated cedar wood charcoal, to be mixed intimately with the flour.—Correspondent.

Vapour Density of Water.—In reference to this subject a correspondent draws attention to a work published many years ago, by order of the French Government, containing the results of the very elaborate researches, made by V. Regnault, on the density, etc., of steam. Our correspondent does not mention the title of the book, but he says that in it the subject mooted by Mr. Ward is fully and conclusively set forth.

Sulphate of Magnesia.—A subscriber wishes to know the name of a firm in the North of England who make sulphate of magnesia by the process described in our journal of April 12th.

Origin of the word Naphtha.—Sir,—I have been trying to trace the origin of the word naphtha, but have not succeeded. Can any of your readers tell me where it was first used to designate an inflammable liquid coming out of the ground?—F. Peterson.

Papering Damp Walls.—Sir,—If your correspondent of last week, R. A. Dudley, will get some of the water-glass or soluble silicate of soda advertised in your columns, and brush the dilute solution several times over the damp wall, allowing it to soak in and dry between each application, he will effect a cure.—E.

Manufacture of Sulphuric Acid.—Sulphurous acid, in presence of much water, reduces binoxide of nitrogen to oxide of nitrogen. Can any of your readers kindly inform me what strength the chamber should work to prevent this? I am working two chambers connected. I should also be glad to know what quantity of nitrate of soda is required to make 20 cwt. of sulphuric acid sp. gr. 1750.—Child.

Plaster of Paris.—I should feel obliged to any of your correspondents who would inform me whether there is any way of causing plaster of Paris to set perfectly hard, so that it cannot be scratched by the finger-nail. I have tried the plan recommended in *Muspratt's Chemistry*, page 462, but do not find it to succeed.—A Working Potter.

Making Pyrogallic Acid.—Sir,—Will any one inform me whether a method has been published whereby pyrogallic acid can be made in the wet way from gallic acid? The process of sublimation usually adopted is tedious and uncertain. Some years ago a variety of pyrogallic acid in hard prismatic crystals was introduced in photography; this was evidently crystallized from an aqueous solution. Query—Was it sublimed first and crystallised afterwards, or was it not rather prepared in the wet way?—I. Couper.

Iron made Red-hot by Hammering.—Sir,—In answer to "Sceptic" (Chemical News for August, 1867), I beg to state that it is a common thing for a good blacksmith to hammer a horse-shoe-nail red-hot upon a common anvil. I have seen it done by one Jesse Stubs repeatedly, who informed me that "years ago when he was a lad," it was not an uncommon thing for a journeyman blacksmith on applying for work, to have to prove himself a good hammerman by making a nail red-hot in as few a number of strokes as possible. I once produced a blacksmith and anvil at a lecture, before the Royal Literary Institution of Hull, when the man made the nail glow before the audience by hammering it. Old blacksmiths in the country say that before the days of Congreve, Letchford, or Bryant and May, they many a time lighted their forge fire of a cold morning by means of a nail made red-hot by converting motion into heat, or as they term it, "a few sharpish taps" with a hammer. Let "Sceptic" go to a large blacksmith shop and offer a shilling to every man who will hammer a nail red-hot, and unless blacksmiths have degenerated during the late severe winter, he will soon part with his money.—J. W.

Mercerising Cotton.—Sir,—There is no doubt that Mr. Mercer's discovery mentioned in your present number, is a valuable one, and were the objections to it more generally known, some of your talented readers might succeed in overcoming them. The advantages are that the fabric contracts about one-fifteenth linearly in each direction, and the threads appear rounder, firmer, and closer together: the cloth does not reflect so much white light, but has a translucent appearance. Its strength is also improved; cotton thus treated shows a superior affinity for some colours, especially indigo-blue; it takes as deep a shade of blue in one dip as common cloth takes in six, and, generally speaking, colours look better on this than on untreated cloth. The objection to the process was mainly the expense of the soda, but now that this agent has been reduced in price this objection will not be so formidable. It was also said that the appearance of greater fineness and closeness, produced by the contraction of the fibre, could be more surely and economically produced by the loom.—F. Oglevie.

⁂ *With reference to Mr. Ward's figures in our last number, we feel it right to mention that we printed them from a private note, evidently written off-hand, and unrevised: as also that the writer's corrected version reached us by the post following that by which the* Chemical News *would come into his hands, and antedated the other letters on this subject. The fact of Mr. Ward's letter following instead of preceding the other letters occurs in accordance with a rule adopted in most printing-offices, when there are several communications on the same subject, of placing the shortest first.*

ANSWERS TO CORRESPONDENTS.

⁂ All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E. C. *Private* letters for the Editor must be so marked.

⁂ In publishing letters from our correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

We have been requested to correct an error which has been very generally made by the English Press (the Chemical News included). In the list of firms which have gained silver medals at the Paris Exhibition, the well-known firm of *Morson & Son* has been misprinted *Mancson*.

Clericus.—The powder for Larkin's magnesium lamp can be obtained at the magnesium metal company, Manchester; apply to Mr. Mellor, manager.

Querist.—Apply to F. Viewig and Son, Publishers, Brunswick, for the works of Baron V. Liebig.

J. F.—The substance is sesquioxide of iron; but whether derived from the pipe or deposited from the water, we cannot say. Is the pipe corroded?

Edward, O.—You will be able to obtain all the information you require by applying at the Patent Office, Southampton Buildings, Chancery Lane.

A New Subscriber.—Our first volumes can occasionally be procured second hand. Our publisher is sometimes able to secure a set. Leave your name at our office, and state how much you are inclined to give for Vols. I. and II.

Dr. A. L. P.—We regret that your communication is too long for our columns.

F. Robson.—Pyrophosphate of soda in solution will dissolve sulphur, forming a polysulphide.

F. Huddersfield.—Scheele's green is arsenite of copper. Schweinfurt green is mixed arsenic and acetate of copper. If chromium green will be bright enough for what you want we certainly advise you to use it in preference.

J. S.—We have been unable to find the paragraph in question; about what date did it appear?

W. H. A.—There is no difficulty in taking ink stains from paper. Most acids will effect the desired object. The principal thing to be attended to, is to remove every trace of the acid from the paper after it has done its work. This is a difficult thing to do properly, and its neglect is the cause of the rotting so often complained of after the removal of ink-spots.

W. J. S.—The term photograph is the generic name applied to all pictures taken by the agency of light. A daguerreotype is, therefore, as much entitled to be called a photograph, as a paper print from a collodion negative.

A Druggist.—Picrate of Potash has been used by Braconnot as a substitute for quinine, in intermittent fevers; the dose is from two to five grains. It was said to answer very well, but makes the patients as yellow as guineas.

D. R.—Sulphate of baryta is soluble in hot strong sulphuric acid, but water precipitates it.

A Manufacturer.—If you advertise in our pages you will be certain to receive many answers.

S. Johnson.—To dye silk with gold, immerse the stuff in a bath of chloride of gold for ten minutes, then wring and dry. Expose to the sunlight, when the colour changes to a beautiful lilac.

Papering Damp Walls.—Sir,—One of the walls in my house is so damp that the paper will not stick; it mildews and peels off within a few months. I am not a chemist, but I should think that some of your correspondents will be able to suggest a remedy.—R. A., Dudley.

Errata.—Page 113, line 16 from the top, *for* carbonate of soda, *read* carbonate of ammonia; page 117, line 2 from the bottom, *for* 1863, *read* 1836.

B. H. A.—Nitrite of amyl may be prepared by passing nitrous vapours into amylic alcohol contained in a heated retort, rectifying the distillate, and collecting apart the portion which goes over at 90 deg. C.

James P.—Your problem in hydrostatics fails in one important requisite: you have forgotten to allow for the force of gravitation.

A. L. S.—It would be a breach of confidence to impart the information, even if we possessed it.

Barium.—Your communication is declined with thanks.

Medicus.—One of the best hæmostatic agents is said to be a mixture of perchloride of iron and common salt, dissolved in water. No free acid must be present.

M. Kestner.—The best examination of the fixed line D of the solar spectrum was given with a diagram, by Professor Cooke, in our number for July 4, 1863. The drawing shows eight sharp lines, and a nebulous hand between the two constituents of D.

Junior Student.—The diaphanometer is an instrument proposed and employed by Saussure for measuring the transparency of the air. Its action was very imperfect, and any variation in the acuteness of the observer's sight would vitiate its results.

A. B.—There is no danger. Push the heat as far as you can.

Zena.—Don't be misled, the book is a very good one.

W. Thomson.—Silver solder is best for uniting steel together. Make it by melting together 10 parts of silver, 1 part of copper, and 1 part of brass. Use borax as a flux.

C. Chase.—You had better consult a solicitor. We would rather not advise in such a case.

Dyer.—Stannate of soda is now generally employed. See if your sample contains tungstate of soda. The stannate contains 9 equivalents of water of crystallization. It is efflorescent in a dry atmosphere.

Foreign Science.—Up to the time of going to press we have not received the Abbe Moigno's letter, nor the proceedings of the *Academie des Sciences* for Monday last.

D. Waldie.—Our correspondent's communication is received with thanks. We shall always be pleased to hear from him.

Communications have been received from W. Briggs; W. Huskisson; Prof. Williamson, F.R.S.; F. Field, F.R.S.; Dr. Odling, F.R.S.; C. Greville Williams, F.R.S.; Dr. R. Angus Smith, F.R.S.; D. Forbes, F.R.S.; C. S. Read; P. Jessop; R. Lowe; C. R. Wright, B.Sc.; John Robinson (with enclosure); G. F. Rodwell, F.C.S.; E. Kierman (with enclosure); Alex. Glendining; Prof. G. G. Stokes, F.R.S.; Dr. Letheby; G. A. Keyworth; H. Bywater (with enclosure); J. Wallace; J. H. Swindell; Prof. Daubeny, F.R.S.; Joseph Davies (with enclosure); Edmund G. Tosh (with enclosure); Lewis Demuth and Co.; J. T. Atkinson; W. Ladd; Hood; F. A. Abel, F.R.S.; Dr. Letheby; W. B. King; Morson and Son; H. B. Condy; Sir B. C. Brodie, Bart. F.R.S.; Dr. F. C. Calvert, F.R.S.; B. Westermann and Co. (New York); G. Hill; H. Woodward; D. Forbes, F.R.S.; G. F. Rodwell; E. Beanes; Dr. Odling, F.R.S.; W. Bright; Albright and Wilson (with enclosure); J. Kayess; C. R. C. Tichborne; Muspratt Bros.; Dr. Oxland; John Filley; Professor Williamson, F.R.S.; J. Ilif; T. Sterry Hunt, F.R.S.; H. Burgoyne; L. Twining (with enclosure); A. S. Herschel; J. Ingram (with enclosure); J. Layton with enclosure); C. Greville Williams, F.R.S.; Henry Woodward; F. Bright; C. R. C. Tichborne; J. N. Vinen; the Metropolitan Association of Medical Officers of Health; S. W. Moore; T. Landaner (with enclosure); George Lunge; C. Foster, B.A.; Ludwig Mond; W. M. Watts, B.Sc.; Dr. F. C. Calvert, F.R.S.; C. R. C. Tichborne; Gossage and Son (with enclosure); Jesse Fisher, do.; Benjamin Wheeler, do.; G. Eccles, do.; Smith and Sons, do.; J. Sampson, do.; J. Thom, do.; W. Blyth, do.; W. M'Leod, do.; H. Eve; C. R. A. Wright, B.Sc.; W. Kunde; F. Hughes; R. C. C. Lippincott; D. Waldie (Calcutta); J. D. Dana; Professor How, D.C.L.; Dr. August Stromeyer; F. O. Ward; Captain R. F. Burton (with enclosure); A. P. Hurlstone; S. Norman; Dr. P. Williams; B. Quaritch; J. Foord (Victoria); J. Thom (with enclosure); John Lundy.

Books Received.—"Researchess on Gun Cotton," by F. A. Abel, F.R.S., being the Bakerian Lecture for 1867; "Crystallogenic and Crystallographic Contributions," by James D. Dana.

THE CHEMICAL NEWS.

Vol. I. No. 4. American Reprint.

NOTES ON SOME COMPOUNDS OF PALLADIUM.

BY HENRY CROFT,

PROFESSOR OF CHEMISTRY, UNIVERSITY, TORONTO.

Palladio-bichloride of potassium is best prepared by passing chlorine through a concentrated hot solution of the palladio-protochloride. Almost the whole of the metal is precipitated as a double salt of a fine colour. What remains in solution may be advantageously employed in preparing the chloride of palladammonium.

The double salt $PdCl_2KCl$ exhibits a remarkable change of colour on the application of a moderate heat, turning quite black, and resuming its scarlet colour on cooling. If heated too strongly it fuses, loses chlorine, and, on cooling, is of a brown colour, being converted into the palladio-protochloride.

Cyanide of Palladammonium, originally described as ammoniated cyanide, is readily obtained by adding HCy to a solution of NH_3PdCl. It forms a white crystalline powder, soluble in hot water. Analysis showed it to be Fehling's salt.

Sulphide of Palladammonium.—When dilute $\left.\begin{matrix}H\\H\end{matrix}\right\}S$, or very dilute $\left.\begin{matrix}NH_4\\H\end{matrix}\right\}S$ is added to a solution of $\left.NH_3\begin{matrix}Pd\\Cl,\end{matrix}\right\}$ a bright red or orange red precipitate is formed, much like the sulphide of antimony; it changes very rapidly into brown or brownish black sulphide of palladium.

Double Sulphocyanides.—These may be obtained in precisely the same manner as the platinum compounds described by Buckton. The potassium salt forms ruby-red crystals, which can be obtained of considerable size, soluble in water and alcohol. The latter solvent was used for separating it from the chloride. The salt is anhydrous, melts at a high temperature, gives off sulphur and bisulphide of carbon, and is oxidised by nitric acid, forming a white compound free from sulphur, apparently analogous to Claus's product. The solution of the potassium salt precipitates various metallic solutions, forming apparently corresponding insoluble palladio-sulphocyanides.

Similar compounds can be obtained from the palladio-protochloride. The potassium compound forms dark red needles. From the few analyses I was able to make, the composition of all the above salts seems to be the same as that of the platinum compounds.

By acting on the potassium salts with ammonia, a salt is obtained crystallising in fine reddish brown needles; the same can be obtained by acting on chloride of palladammonium with sulphocyanide of potassium in the same way as recommended by Buckton for the platinum salt.

The analysis gave the formula $\left.NH_3\begin{matrix}Pd\\Cy\end{matrix}\right\}S$—sulphocyanide of palladammonium.

The sulphur is oxidised with great difficulty, even by hydrochloric acid and potassic chlorate.

Several compounds of palladammonium with organic acids, especially nitro-acids, are well crystallised, more particularly the trinitro-phenylate or carbazotate.

ON THE MANUFACTURE OF NICKEL.

BY DR. AUGUST STROMEYER.

The following communication concerning the production of nickel, will, no doubt, interest some of your readers. The method employed was kept a secret for a long time, and is partly so even now.

Formerly, nickel was produced from the speiss obtained in the making of smalt, but since the perfection attained in the manufacture of artificial ultramarine, smalt has not been so much in demand; less has therefore been made, and the old stores of speiss have been used up.

Recently some speiss has been produced from copper and silver ores containing nickel. These ores are smelted with pyrites, by which means the copper and silver are concentrated in the sulphide of iron. If the ore contains nickel in combination with arsenic (if not, arsenical pyrites is added), a bright heavy regulus composed of arsenic, nickel, and cobalt, called speiss, will be found beneath the slag.

By an oxidising smelting, the speiss becomes purified, so that only arsenical nickel remains.

The speiss, in a pure state, has the composition Ni_2As (52 per cent. of nickel); ordinarily, it contains iron, cobalt, bismuth, lead, antimony, and sulphur.

By smelting the speiss, or any nickel ore in contact with atmospheric air, and a reagent capable of fluxing the resulting oxide, pure arsenical nickel (Ni_4As) is obtained. The remaining separation of arsenic from the nickel is very difficult.

The following process for the production of nickel is that used at Dittenberg (Nassau). The ore is iron pyrites containing *capillary pyrites* (NiS), and occurs in veins of serpentine. Besides the nickel ore, a copper ore is also worked. The nickel ores are not previously prepared, as the matrix gives a suitable slag.

The average composition of these ores is:—

Dolomite	CaO,CO_2	8·07
	MgO,CO_2	8·13
Sparry iron ore	FeO,CO_2	22·86
Copper pyrites	$Cu_2S+Fe_2S_3$	21·98
Nickeliferous pyrites	$\left.\begin{matrix}\frac{3}{5}Ni\\\frac{2}{5}Fe\end{matrix}\right\}S$	6·88
Bismuth glance	BiS_2	2·05
Iron pyrites	FeS_2	7·72
Red hæmatite	Fe_2O_3	11·61
Quartz	SiO_2	10·33
Moisture		0·27
As,Co,KO,NaO		0·30
		100·20

Other analyses make the nickel to exist as capillary pyrites (NiS)—this mineral is seen now and then in the ores. The ore yields on an average 3 per cent. of nickel and 5 per cent. of copper. In 1857, Heusler introduced a process for the production of a nickel-copper alloy similar to the Swedish one.

The process may be divided into four parts.

1. **Raw Melting.**—Roasting the ore and smelting it to coarse metal.

2. **Concentration Melting.**—Roasting the coarse metal and smelting it to a concentrated regulus.

3. **Refining Melting.**—Separation of the iron from the concentrated regulus.

4. **Roasting and Reducing Process.**—Transformation of the regulus into oxides of copper and nickel by roasting, and reduction of the oxides to copper-nickel.

1. **Raw Melting.**—The ore is crushed to pieces of the

size of a man's fist and roasted in kilns. On the sole of the furnace are bedded about $\frac{1}{16}$ cwt. of charcoal, then ¼ cwt. of brown coal, then 15 cwt. of ore, then again ¼ cwt. of brown coal, and finally 25 cwt. of ore. The charcoal at the bottom is lighted, and, after 12 hours, the roasting will have proceeded so far that three-fourths of the ore may be taken out of the furnace as being well roasted. Brown coal and ore are again put on in layers. 100 cwt. of roasted ore is mixed with 63 cwt. of slag from the former melting, and smelted with coke in a furnace. This is filled with charcoal, which is lit and allowed to burn down a little, which having taken place, one barrow of coke and two of slag are put on and the blast-engine worked. Two barrows of mixture are now put on to one of coke, and by a gradually increasing amount, seven or eight barrows of mixture are added within a few days to one of coke. (One barrow of coke=20lbs.; of mixture=30lbs.) The silicious slags from the copper-ore smelting are the most convenient to employ. One operation usually lasts six weeks.

2. **Concentration Melting.**—The regulus is now stamped and passed through sieves. It is then roasted in a reverberatory furnace. The charge of the furnace is 10 cwt., the volume of which becomes doubled by roasting.

The firing in the beginning of the process is kept low, as the heat increases by the oxidation of the charge. After two hours the heat is raised, till at the end of the process it reaches a white heat. During the last two hours powdered charcoal is added to decompose any sulphates formed.

Sohnabel has made most careful analyses of the regulus removed at different times during the process. From these it is found that the desulphurisation takes place gradually.

The regulus still contains 7 per cent. sulphur. It is again smelted, being now mixed with 1 per cent. of lime. 100 cwt. is prepared with 67 cwt. of silicious copper cinders, poor in oxide. The charge commences with 2 barrows of preparation to 1 barrow of coke, and the proportion increases to 5 or 6 barrows in 24 hours.

3. **Refining Melting.**—This melting operates as an oxidation process, and is used to separate completely the iron. It is carried on in a copper refining furnace with silica. Here the concentrated regulus is smelted with coke, when it melts and falls in drops to the bottom of the furnace. The iron remains in the slag as silicate of protoxide of iron, which is easily fusible.

To melt 170 lbs. of regulus it takes about 1¾ hours. The fuel is now taken out of the furnace, and the slag on the surface of the metal, cooled by a blast and renewed. The process is renewed with fresh flux, and repeated until the slag possesses an enamel-like appearance, a proof of the separation of the iron. The resulting metal is melted and drawn off by a gutter in the smelting hearth.

4. **Roasting and Reducing Process.**—The nickel-copper regulus thus obtained is now converted by roasting into oxides of nickel and copper. For this purpose it is ground to powder and sifted through very fine sieves; 4 cwt. of the powder are spread out on the hearth of a reverberatory furnace, and are roasted for 12 hours, being continually and thoroughly stirred up. The regulus by this roasting becomes desulphurised till it contains not more than ¾ per cent. The powder is then again roasted for 8 hours, at first at a red heat, and finally at a white heat. By this treatment all the sulphur, and also the small amounts of antimony and arsenic still retained, are separated.

The manipulation used in this latter process is kept a secret. The writer presumes that the regulus is mixed with carbonate and nitrate of potash; by heating with this mixture sulphantimoniate and arseniate of potash would be formed,—compounds soluble in water. The oxides of copper and nickel have now only to be reduced to the metallic state. The moistened oxide, in charges of 150 or 200 lbs., is reduced in a charcoal furnace.

The slags contain nickel and copper, partly scorified, partly mechanically suspended. They are reserved for re-smelting.

The result of the process just described is an alloy of copper and nickel; the nickel is therefore in a convenient form for use in the manufacture of German silver.

ON THE INACTIVE CONDITION OF SOLID MATTER.

In the Chemical News for Nov. 30, 1866, we gave an account of some remarkable experiments by M. Gernez, as recorded in the *Comptes Rendus* for 19th November, 1866. It is well known that when a solid body, such as a glass rod, is introduced into soda water, seltzer water, or other supersaturated solutions of gas, it becomes immediately covered with gas bubbles, and even effervescence may set in. The rod, however, becomes inactive after a short time, or it may be made so by previously immersing it in water, or by heating it in the flame of a spirit lamp, or by keeping it out of contact with air. The theory is that it is not the solid that disengages the gas from its solution, but the air in contact with such solid. The inactive solids become active if exposed to the air for a quarter-of-an-hour or an hour. Every solid, however smooth, is covered with roughnesses that form a sort of network of capillary conduits, into which surrounding gases penetrate and condense; and the gas bubbles thus imprisoned act as centres of force in liberating gas from solution. The rougher the body the more brisk the effervescence. The disengagement of gas ceases in time, since each bubble carries with it a portion of the gas which produced its liberation. Heat expels the gas from the surface of the solid by expansion, and immersion in water by solution.

In order to support this view, the author relies upon the following experiment:—"I introduced into a supersaturated aqueous solution of carbonic acid an almost capillary tube, closed at one end, and inverted like a gas-jar, and containing air. I had previously deprived this tube of the property of liberating gas. Immediately after immersion, gas adhered to the column of air which the tube contained, forming quickly a large bubble, which was disengaged; then another was produced, and so on. The gas formed then only at the point where the liquid touched the column of air. From this experiment, which I have varied in several ways, it may be concluded that air liberates carbonic acid from its aqueous solution." It is further stated that the nature of the gas is of no consequence, for "supersaturated solutions lose their gas under the influence of any gas bubbles whatever."

In the August number of the *Philosophical Magazine* Mr. Tomlinson, F.R.S., of King's College, combats the above theory, and denies that air or gas has any action in liberating gases from their solutions. The theory that he proposes to substitute rests on the distinction between a chemically clean solid and one that is clean in the ordinary sense of the word. If the solid be chemically clean there is perfect adhesion between it and the solution, and there is no liberation of gas; if the solid be not chemically clean, then the adhesion is imperfect, and there is a separation of gas. If the water is not attracted by the solid, the gas is; for although the rod may not be clean enough for water to adhere to it, yet gas will adhere to a dirty or a greasy rod. If the rod be made chemically clean it soon ceases to be so by exposure to the air; and this circumstance, according to Mr. Tomlinson, has led the numerous writers on supersaturated solutions of salts into error as to the action of *nuclei*, etc., in inducing crystallisation. If the nucleus be chemically clean, the solution wets it perfectly, and there is no separation of salt from the water; if the nucleus be not chemically clean the adhesion is differently distributed between the water and the salt, or the water and the gas, and there is a separation. According to this view a chemically clean body which appears to be "inactive," is really most active; while the so-called "active" condition is really one of imperfect adhesion.

We select a few of Mr. Tomlinson's experiments in support of this novel view, which, if admitted, will throw a great deal of light on a very obscure object:—

Experiment 1. Two ordinarily clean test-glasses, A and B, were taken; A was first filled with methylated spirits of wine and then rinsed with abundance of water. A bottle of soda water was now poured gently into the two glasses. The inner surface of B was profusely covered with gas bubbles, but not a single bubble was seen on the surface of A.

Experiment 2. A glass rod and a platinum spatula were dipped into A and B, and produced abundant effervescence. They were dipped into spirits of wine, rinsed, and again put into A and B. Not a bubble of gas appeared on either surface, except above the points at which the bodies had been made chemically clean, and there numerous gas bubbles appeared. Indeed it was accurately determined by the formation of these bubbles how far the solids had been dipped into the spirit.

Experiment 3. A rat's-tail file made chemically clean did not liberate any gas; but dried and drawn through the moist hand (experiment 4) it liberated gas abundantly.

In like manner dry iron filings (experiment 5) that produced effervescence, did not do so after being washed in spirit; when thrown wet into soda water the spirit was of course displaced by the liquid, and the filings were wetted by it, and yet there was no liberation of gas.

A wire gauze cage (experiment 7) full of air was lowered into soda water and there was no escape of gas so long as the cage was chemically clean; when the cage was handled with dirty hands (experiment 8) and put into the soda water there was an abundant effervescence.

Experiment 9. A glass rod was heated in oil above 300° F.; then wiped with a duster and put into soda water. It was instantly and completely covered with gas bubbles.

Experiment 11. A large fragment of flint was broken into two pieces and put into soda water. Gas was abundantly liberated except from the two new and chemically clean surfaces, and on them not a bubble was seen.

Experiment 12. A narrow tube eleven inches long was kept in spirits of wine for an hour for five inches of its length. It was closed at top and so lowered into soda water. There was no liberation of gas either from the tube or the column of air in contact with the solution. On removing the finger, the solution ascended the tube, but there was no liberation of gas until the solution touched that part of the tube which had not been immersed in the spirit, and from this gas was liberated both from the outside and inside of the tube. It is remarked that had M. Gernez made the inside of his tube as "inactive" as he made the outside, he would have seen that the column of air had really no action in liberating the gas.

ON THE

UTILISATION OF THE WASTE PRODUCTS OF THE MANUFACTURE OF COAL GAS.

BY DR. LETHEBY.

(Continued from page 127.)

LOOKING, therefore, at the compositions of the principal products of coal tar distillation, it may be said that the *crude naphtha* contains certain alliaceous oils, with benzole, toluole, xylole, cumole, and a little cymole, besides the more volatile basic compounds, as pyridine, picoline, lutidine, collidine, and a little aniline, with from 2 to 3 per cent. of carbolic acid and a little naphthaline.

Light oil contains cumole, cymole, and the other less volatile hydrocarbons, with a large amount of naphthaline, and the denser alkaloids, as collidine, aniline, toluidine, and even a little chinoline; besides which it contains from 10 to 20 per cent. of carbolic and cresylic acids.

Heavy oil consists chiefly of hydrocarbons which have not been well studied, and the bases which have a high boiling point, as chinoline, lepidine, and cryptidine, with small quantities of cumidine and cymidine, and from 7 to 10 per cent. of carbolic and cresylic acids.

Carbolic acid ($C_{12}\ H_6O_2$), or as it is sometimes called *phenic acid*, is largely in demand for making dyes and for disinfecting purposes, and it is most profitably extracted from the light oil before it is distilled for benzole, etc. The naphtha which flows over between 300° and 400° Fahr., and which has a gravity below 900, is best suited for the preparation of carbolic acid; for although there is much acid in the heavier oils, yet they are so nearly of the same gravity as the alkaline solution used in extracting it that there is great difficulty in separating them. The light oil is well shaken with about one-third of its bulk of a solution of caustic soda of from 14° to 16° Twaddle (1·07 to 1·08 sp. gr.) and containing from 5 to 7 per cent. of alkali. After standing for some time the oil separates, and the alkaline liquor may be drawn off by means of a syphon. This is to be neutralised with sulphuric or muriatic acid, and then the carbolic acid floats as a dark brown oil. This is the crude acid of commerce, and when purified by means of sulphuric acid and careful distillation from chloride of calcium, it forms the camphor-like substance which you here see. It has a peculiar creosote-like smell, and when largely diluted with water, even to the extent of 1 part in 10,000, it has a sweet taste. It is a very powerful caustic, turning the skin white and quickly raising a painless blister. The specific gravity of the pure acid is 1·065. It melts at from 95° to 98° Fahr., but the merest trace of water will lower its melting or congealing point, so that this is the test of the quality of the acid. It boils at 369° or 370° Fahr., and its vapour burns with a sooty flame. If it be passed through a red-hot tube it is decomposed, forming naphthaline and other hydrocarbons; and if it be heated for some time with ammonia in a closed tube, at a temperature of from 400° to 500° Fahr., it produces aniline and water thus:—

$$\underbrace{C_{12}H_6O_2}_{\text{Carbolic acid.}}+NH_3=\underbrace{C_{12}H_7N}_{\text{Aniline.}}+2HO$$

It combines with alkalies to form salts, but the combination is very feeble, for the acid is set free by heat and even by the carbonic acid of the atmosphere, so that the common preparation of it, carbolate of lime, slowly evolves carbolic acid when it is exposed to the air.

The acid is a very powerful antiseptic and disinfectant. It is especially destructive of the lower forms of organic life, and hence, perhaps, its value as a disinfectant. Several varieties of the acid are now prepared and sold for general and medical purposes, and the experience of the last few years has proved it to be an important hygienic agent. Its use in the preparation of dyes will be explained directly.

The other acids of coal tar, as *cresylic* ($C_{14}H_8O_2$), *phlorylic* ($C_{16}H_{10}O_2$), *rosolic* ($C_{24}H_{12}O_6$), may be obtained by the use of a stronger alkaline solution as recommended by Laurent. A saturated solution of potash, added to the mixed light oil and heavy naphtha, and then treated with a little powdered caustic potash, will produce a magma from which the unattacked liquid oil may be separated. By dissolving it in a small quantity of water and allowing it to stand, it separates into two layers—an upper oily layer which is of no use, and a lower layer which contains the tar acids. When this is neutralized with muriatic acid, the crude acids float as an oily layer, and may be separated from each other by fractional distillation.

IV.—SPENT OXIDE OF IRON.

This is the next substance in order of the purification of coal gas. In its fresh state the hydrated peroxide of iron freely absorbs the sulphuretted hydrogen of foul gas, forming the black sulphide of iron. On exposure to the air the iron again absorbs oxygen, and becomes revived—the sulphur which it had before taken in as sulphuretted hydrogen being set free among the particles of the oxide. In this manner, by a succession of foulings and revivifications, the oxide becomes so charged with sulphur as to be unfit for use. It then contains from 35 to 57 per cent. of sulphur, the average being about 42 per cent.; and although it is useless at the gas-works, it is of some value in the production of oil of vitriol. Special furnaces, however, are necessary for its combustion, for as it contains about 20 per cent. of sawdust it is not capable of being used in ordinary sulphur furnaces. At Messrs. Lawes and Messrs. Hills, where I have seen the spent oxide largely used for making sulphuric acid, the furnaces are constructed with very long flues, for the purpose of completely burning the organic vapour before it enters the vitriol chamber. Each furnace is about 12 feet long and 18 inches square, with a floor of fire-brick, upon which the oxide burns. It takes about 2½ cwts. of oxide at a charge, and it burns continuously for twelve hours. The air is admitted by a sliding door in front, and the gaseous products are conveyed from the furnaces, which are placed side by side, and in three tiers over each other, to a common flue at the back, and this is extended backwards and forwards, below and above, so as to prolong the combustion to the greatest extent before the vapours enter the vitriol chamber, for if the combustion is not complete there is a considerable waste of nitre; as it is, indeed, the quantity of nitre used for the oxidation of the sulphurous acid is always about half as much more as is required with native sulphur or pyrites. I think the process might be very considerably improved by continuous instead of intermittent burning, and there is no reason why the use of sawdust may not be abandoned altogether, and spent oxide employed in its place.

V.—SPENT OR REFUSE LIME.

This is generally a very profitless material—in fact, the blue billy from the wet lime purifiers is incapable of any sort of application but that of luting. Dry lime, however, is not so unmanageable a product, for if it it is treated properly it need not occasion offence; and when it is well weathered it is of some value to the farmer. Professor Voelcker has inquired very fully into this matter, and he states that it is useful to certain soil on the following account:—

1. It improves the texture of stiff clay soils by lightening them, and of light sandy soils by giving them solidity.
2. It neutralises the acidity of some soils, and breaks up the organic matter of soils which are too rich in humus, making them more fit for the sustenance of plants.
3. It acts on the granitic constituents of a soil, and sets free the alkalies, thereby making the mineral elements of it available as food for the plant.
4. It supplies food to the plant in the form of sulphate of lime, which is especially useful to the leguminosæ.

And he concludes that well weathered gas lime, judiciously applied to a proper soil, is most useful to many plants, as clover, sainfoin, lucerne, peas, beans, vetches, and turnips; and that it is a good fertilizer, for permanent pasture, especially if the land is deficient of lime. On natural grasses the best farmyard manure often produces but little improvement until a dressing of lime, marl, or gas lime has been applied to it: the latter, more particularly, destroys the coarser grasses, and favours the growth of a sweeter and more nutritious herbage. It also destroys moss, heath, feather-grass, and other plants which are characteristic of peaty land. It is, therefore, especially suited for the improvement of such land; and so it is for the land which is deficient of lime, and which causes turnips to become warty, and be affected with the disease called "fingers and toes." For this it has been found a complete remedy. It may be applied in quantities of from one to two tons an acre, and even more where lands are very heavy, or are very peaty; and the best time to apply it is in the autumn, when vegetation is dormant, so that it can not only weather before the spring returns, but also act on the land during the whole of the winter.

One special precaution is that the lime should never be used in its fresh state, when it contains sulphide and sulphite of calcium in such proportions as to be injurious to plants. The more it is oxidised the better, and, therefore, when it is drawn from the purifiers it should be covered over with old material, so as to prevent smell, and kept until it has lost its activity. The fresh lime contains from 15 to 25 per cent. of quicklime, with a large proportion of sulphide, carbonate, and sulphocyanide of calcium; and even after six or eight months it may still contain a notable proportion of quicklime, with from 20 to 30 per cent of sulphate of lime, a like proportion of sulphite of calcium, and still more of carbonate, in which condition it is not injurious to plants.

In many places farmers are glad to have the material, and will give as much as 2s. a load for it, although the common price is about 1s. a load.

VI.—Acid and other Absorbents of Ammonia.

At the end of all the purifiers there may be placed the material which has been patented by Messrs. Sugden and Maryatt. It is made by moistening sawdust with sulphuric acid slightly diluted with water, and heating it in a retort. The woody matter is in this way charred by the acid, and contains from 30 to 45 per cent. of free sulphuric acid. When it is exhausted by being charged with ammonia, it contains 40 to 60 per cent of salt, which is easily washed out of it, leaving the charred sawdust ready for another charge of acid. The material, with the sulphate of ammonia in it, is fit for conversion into manure, and is worth £5 or £6 per ton. Another absorbent of a like nature is that used by Mr. Croll. It is made from the spent chloride of manganese from the bleaching-works by adding it to chalk and sawdust, and when saturated with ammonia, it contains from 39 to 40 per cent. of muriate of ammonia, which is easily obtained from it either by washing or subliming.

These are several waste products of the manufacture of gas, and it will be seen that, in the aggregate, their value is not inconsiderable provided they are utilized to the fullest extent.

Coal-Tar Colours.

I will now make a few remarks on the processes which are followed for the production of coal-tar colours. Most of them are derived from the naphtha which is sold as 40 per cent. benzole, which is a mixture of benzole and toluole with a little xylole. The first step of the process is to convert the constituents of this naphtha into the corresponding nitro-compounds, by carefully mixing it with fuming nitric acid or with a mixture of two parts of common nitric acid and one sulphuric. The reaction is very violent if the temperature is not controlled; but, with proper management, the three hydrocarbons lose each an equivalent of hydrogen to a like proportion of oxygen in the nitric acid, and gain the residual peroxide of nitrogen. Thus:—

$$\underbrace{C_{12}H_6}_{\text{Benzole.}} + HNO_6 = \underbrace{C_{12}H_5NO_4}_{\text{Nitrobenzole.]}} + 2HO$$

$$\underbrace{C_{14}H_8}_{\text{[Toluole.}} + HNO_6 = \underbrace{C_{12}H_7NO_4}_{\text{Nitrotoluole.}} + 2HO$$

$$\underbrace{C_{16}H_{10}}_{\text{Xylole.}} + HNO_6 = \underbrace{C_{16}H_9NO_4}_{\text{Nitroxylole.}} + 2HO$$

These three nitro-compounds constitute the dark amber-coloured, oily liquid which floats upon the acid; and when it is separated from the acid and washed with water, and then with a weak solution of carbonate of soda, it constitutes the crude nitrobenzole which is used for the manufacture of aniline colours.

It has a strong odour of bitter almonds, is heavier than water, and is very soluble in alcohol and ether. If this crude nitrobenzole be submitted to the action of a reducing agent, each of the nitro-compounds will lose its four equivalents of oxygen, and gain two of hydrogen, and be thereby converted into a corresponding alkaloid, thus:—

$$\underbrace{C_{12}H_5NO_4}_{\text{Nitrobenzole.}} + 6H = \underbrace{C_{12}H_7N}_{\text{Aniline.}} + 4HO$$

$$\underbrace{C_{14}H_7NO_4}_{\text{Nitrotoluole.}} + 6H = \underbrace{C_{14}H_9N}_{\text{Toluidine.}} + 4HO$$

$$\underbrace{C_{16}H_9NO_4}_{\text{Nitroxylole.}} + 6H = \underbrace{C_{16}H_{11}N}_{\text{Xylidine.}} + 4HO$$

This process of reduction may be effected by sulphide of ammonium (Zinin's method), or by the nascent hydrogen evolved when zinc is treated with dilute sulphuric acid (Hofmann's method), or by acting on the nitro-compounds with iron and acetic acid (Bechamps' process). I show you here an experimental illustration of each of these processes, and you will observe that for lecture experiment the process of Hofmann is the most striking, but in practice the method of Bechamps is the most economical.

One hundred parts of the crude nitrobenzole is mixed with nearly its own weight of strong acetic acid, and to this is added, little by little, about 150 parts of iron turnings. The mixture is generally made in an iron retort, and after being well stirred it becomes hot, and soon forms a pasty mass of oxide of iron with an acetate of aniline and the other bases. The reactions are somewhat intricate, but they may be practically expressed thus—

$$\underbrace{C_{12}H_4NO_4}_{\text{Nitrobenzole.}} + {}_4Fe + {}_2HO = \underbrace{C_{12}H_7N}_{\text{Aniline.}} + {}_2(Fe_2O_3)$$

And the same for the other nitro-compounds, so that theoretically the acetic acid should act indefinitely.

The mixture is then submitted to heat until the retort is nearly red hot, by which means impure aniline, etc., distils over, and when this is treated with a slight excess of lime or soda, and again distilled, it yields the crude aniline of commerce. The best product is obtained when the distillation is going on between the temperatures of 340° and 380°, for as the temperature rises to 626° two new alkaloids are produced, which Hofmann has named *paraniline* ($C_{24}H_{14}N_2$) and *xenylamine* ($C_{24}H_{11}N$).

Other processes have been suggested for the production of aniline and its homologues from the nitro-compounds; thus Kremer has recommended the use of finely powdered zinc; Wöhler, an alkaline solution of arsenious acid; Wagner, the ammoniacal solution of suboxide of copper; and Vohl, an alkaline solution of grape sugar; but none of these methods have taken the place of Bechamps'.

The crude aniline of commerce, which is a mixture of aniline and toluidine, is more or less deeply coloured liquid of an amber tint; it is heavier than water, and it acquires a blue or red colour by various oxidizing agents. A solution of chloride of lime turns it, as we see, of a bluish-purple colour. It was this reaction which suggested the name of *kyanol*—blue oil. Acidulated with a mixture of equal parts of water and strong sulphuric acid, and treated with peroxide of manganese or peroxide of lead, it produces, as you observe, a rich blue. Chromic acid makes it, as you may see, of a green, a blue, or a black colour, according to the degree of oxidation; but the most remarkable experiment of all is the coloration of the aniline when it is acidulated with dilute sulphuric acid and submitted to the action of the galvanic battery. At the platinum pole, where oxygen is evolved, it instantly becomes bronze-green, then blue, then violet, and finally red; showing that the coloration of the alkaloid is due to the nascent oxygen, and that the tint corresponds to the degree of oxidation.

The crude aniline dissolves to some extent in water, but it is more freely soluble in alcohol and ether. It readily combines with acids, and forms crystalline compounds; hence it was called *crystalline* by Unverdorben, its discoverer. These salts become coloured on exposure to the air.

The production of colours from this liquid was the remarkable feature of the Exhibition of 1862. It dates from the year 1856, when Mr. Perkin discovered and patented the process for making a rich violet from aniline by means of bichromate of potash; but it is right to say that several chemists had long before noticed the fact that the salts of aniline were capable of producing rich colours. Runge, in 1835, obtained a violet blue by acting on one of the oily constituents of coal tar with chloride of lime. Five years afterwards Fritzsche observed the blue coloration of aniline with chromic acid, and the like thing was described by Beisenhirtz; but none of these reactions commanded attention until the year 1859, when Messrs. Guinon, Marnas, and Bonnet, of Lyons, introduced a new fast purple under the name of *French purple*, which they obtained from orchil, and which became a favourite and fashionable colour. The *mauve* of Mr. Perkin, which had been for three years before the public, was so much like it, that it rose suddenly into public favour. The year after, in 1859, M. Verguin, of the firm of Rénaud Brothers, of Lyons, obtained a brilliant red from the same base, and it was patented by them under the name of *fuchsine*. These two results commanded so much attention that the scientific and technical world entered very earnestly into the investigation with the view of discovering new processes of manufacture; and at the present time we have the means of making almost every variety of tint from coal-tar products. Most of these dyes are called aniline colours, but in truth they are produced from toluidine as well as aniline, and, as we shall see hereafter, they are obtained by processes of oxidation and substitution. They are generally classified under the heads of violets, reds, blues, greens, blacks, yellows, etc.

Violets.

These have received a variety of fanciful names, as *mauve, violine, rosolane, tyraline, insidine, harmaline, imperial violet, regina purple*, etc., etc.

The first of them was obtained in 1856 by Mr. Perkin, whose patent is dated the 26th of August of that year. His process is to add equivalent proportions of diluted solutions of a salt of aniline (generally the sulphate) and bichromate of potash. A good proportion is 2 parts by weight of aniline, 2 of bichromate of potash, and 1 of sulphuric acid of English commerce. The aniline and sulphuric acid are at first mixed and then dissolved in water. To this solution is added the bichromate of potash, also previously dissolved in water, and after being well stirred they are allowed to remain quiet for 10 or 12 hours, when a dark-coloured sediment appears. This is to be collected upon a filter and well washed with cold water. It is then dried and treated with colourless coal-tar naphtha until all brown tarry and resinous matter is dissolved away. After this it is again dried and boiled in successive portions of alcohol or methylated spirit until the whole of the violet colouring matter is dissolved out. The spirit solutions are then distilled in order that the spirit may be recovered, and the residue is mauve. It amounts to only about 4 or 5 per cent. in weight of the aniline used, but its tinctorial power is very great. In this condition it is not absolutely pure, although it is sufficiently so for common purposes. To purify it, it must be boiled in a large quantity of water, and the solution treated with an alkali. The colouring matter which precipitates is to be collected upon a filter, washed with water until all trace of alkali is removed, and then dissolved in spirit. If the spirituous solution be evaporated to dryness, the pure colouring matter remains as a beautiful bronze-like substance. It is hardly at all soluble in water, ether, or coal-tar naphtha; but it freely dissolves in spirit and in weak acids, especially acetic. Concentrated sulphuric acid dissolves it without decomposing it, and forms a dirty green solution, which becomes of a beautiful blue colour with a little water, and a violet or purple with a good deal. It is, therefore, a very permanent body, although it will not resist the action of chlorine or nitric acid. Reducing agents, as sulphide of ammonium or protosulphate of iron, change it to a brown-coloured solution, which re-acquires its violet tint on exposure to the air. Like most of the aniline dyes it forms a very insoluble coloured precipitate with tannin.

Other processes have been patented for making this colour; thus, Bolley, in 1858, Beale and Kirkham, in 1859, and Depouilly and Lauth, in 1860, patented the use of chloride of lime with a salt of aniline. These solutions, when used in proper proportions, produce an insoluble purple precipitate, which is the mauve of Perkin. It is purified by washing it with water slightly acidulated with sulphuric acid, then dissolving it in concentrated sulphuric acid, reprecipitation with water, washing it with water upon a filter, and lastly dissolving in spirit. In 1859 Mr. Kay patented a process for obtaining it by adding peroxide of manganese to a strong solution of sulphate of aniline, and keeping the mixture for some hours at the temperature of boiling water. The purple solution thus obtained is to be filtered and precipitated by adding ammonia until the acid is neutralised, and the precipitate, when collected upon a fiter, washed with water, and then dissolved in spirit, forms the violet-coloured dye called *harmaline*. In the same year Mr. D. Price produced a patent for manufacturing the colour by means of peroxide of lead, instead of peroxide of manganese, and Mr. Greville Williams obtained a patent for permanganate of potash. The year after (1860), there were several patents for it, as Mr. Stark's, with ferricyanide of potassium, and Messrs. Dale and Caro's, with perchloride of copper and chloride of sodium.

In the year 1861, Mr. Adam Girard observed that a purple colour could be obtained from aniline red by mixing it with its own weight of aniline and exposing it for several hours to a temperature of 350° Fahr., which is a little short of the boiling-point of aniline. The mixtures employed were equal parts of dry muriate of rosaniline and aniline, and the product, which is a reduced condition of aniline red, is washed with water slightly acidulated with muriatic acid until all the unacted-on aniline and aniline red are removed, and the pure purple remains. This is dissolved in spirit or acetic acid, and forms the dye called *Imperial purple*. In the year following (1862), Mr. Nicholson obtained his patent for procuring the same colour by merely heating Magenta or aniline red to a temperature of from 390° to 420° Fahr. The substance first melts, and, after evolving ammonia, is changed into the purple which he named *Regina purple*.

Aniline Reds,

called *fuchsine*, *roseine*, *azaleine*, *rosaniline*, *Magenta*, *Solferino*, and other fanciful names, are conspicuous in the American section of the Paris Exhibition of this year. This colour was obtained by Dr. Hofmann as far back as the year 1843, when he was experimenting on aniline with fuming nitric acid; and 15 years later (in 1858) he again obtained it, when he was studying the reactions of bichloride of carbon on aniline. He found, indeed, that when 3 parts of aniline were heated with one part of bichloride of carbon for some time, a resinous mass was produced which furnished to alcohol a rich crimson colour. This was aniline red; but, as he was studying the reactions for other purposes than the formation of coloured products, he merely noticed the fact, and put it upon record. A year after Messrs. Verguin and Rénaud Brothers, of Lyons, discovered and patented their process for making *fuchsine*, or aniline red, from aniline, by means of bichloride of tin; and thus a practical value was given to the scientific researches of Dr. Hofmann. Fuchsine is obtained by heating together 10 parts of aniline and 6 of anhydrous bichloride of tin in a glazed iron vessel for 15 or 20 minutes. The temperature should be about that of the boiling-point of the mixture (392° Fahr.). At first the mixture becomes yellow, then gradually more and more red, until the liquid mass looks black. When this occurs it is allowed to cool, and the mass is treated with a large quantity of boiling water, which acquires a rich crimson colour. This is the dye, and it may be used at once, or purified by adding to it a quantity of common salt, in which solution the dye is insoluble. The precipitated colouring matter is allowed to subside, and, after being collected upon a filter, it is dissolved in spirit, or acetic acid, and so forms the red dye. The process patented by Mr. David Price, in the year following (1859), was to act upon a solution of sulphate of aniline with peroxide of lead, by boiling them together in the proportion of one equivalent of the former to two of the latter, until the solution acquires a deep red colour. This is filtered; and, after being concentrated by evaporation, it is again filtered, to separate a resinous substance which forms in it. An alkali is then added to neutralize the acid, and the colouring matter is precipitated as a dirty brown powder. When this is collected upon a filter, washed with water, and dissolved in spirit or acetic acid, it forms a beautiful red dye, which is fit for use. Messrs. Simpson, Maule, and Nicholson, used this process very largely until the beginning of the year 1860, when Dr. Medlock committed to them his patent for making aniline red by means of arsenic acid. The process now followed is to mix together a highly concentrated solution of arsenic acid with aniline, using the latter a little in excess; a good proportion is 20 parts by weight of syrupy arsenic acid, containing 76 per cent. of the solid acid, and 12 of commercial aniline. In this manner a pasty mass of arseniate of aniline is formed, and, when this is heated for some time at a temperature of about 300° Fahr., it intumesces, and at last forms a dark-coloured liquid, which, on cooling, sets into a resinous solid, with a bronze-like lustre. The crude colouring matter thus obtained is very soluble in spirit or water, and may be at once used for dyeing purposes, but it is better to purify it by adding a slight excess of slaked lime to the aqueous solution, and so precipitating the colouring matter with the insoluble arsenical salts of lime. The mixed precipitates are collected upon a filter, and the colouring matter dissolved out with acetic or tartaric acid. Another and better method of purification is to dissolve the crude mass in dilute muriatic acid; then to filter, and to precipitate by adding a slight excess of alkali (carbonate of soda). The colour thus set free is to be collected upon a filter, washed with water, and then dissolved in spirit and acetic acid.

Another variety of aniline red, the nitrate of rosaniline, or *azaleine*, has been extensively manufactured in England by the process of Mr. Perkin, and in France by that of M. Gerber Keller. Mr. Perkin heats a mixture of aniline, or its homologues, with dry pernitrate of mercury for some time, at a temperature of 347° Fahr. The mixture first becomes brown, and then gradually acquires a dark crimson colour, during which time the mercury is reduced, and settles to the bottom of the fused mixture. On pouring it off, and allowing it to cool, it forms a solid mass of impure nitrate of rosaniline, which may be purified by dissolving in water, and precipitating with common salt. M. Gerber Keller's process is nearly similar, except that he uses a lower temperature. He takes 10 parts of aniline, and 7 or 8 parts of dry pernitrate of mercury, and heats the mixture for several hours in a bath of boiling water. Messrs. Dale and Caro obtain the colour by heating a mixture of equal parts of aniline and powdered nitrate of lead, and then adding little by little a fourth part of anhydrous phosphoric acid. Other processes have also been patented, as that of Lauth and Depoully (1860), with nitric acid; that of Smith (1860), with perchloride of antimony, antimonic acid, peroxide of bismuth, stannic, ferric, mercuric, and cupric oxides; and Gerber Keller has claimed almost every common metallic salt that is known. As might be expected, a number of these processes are practically useless, and have been claimed for no other purpose than that of anticipating the profits of future discoveries.

Aniline Blues,

called *azaline*, *Bleu de Paris*, *Bleu de Lyons*, *Bleu de Mulhouse*, etc. Soon after the discovery of aniline red, it was observed that certain reducing agents had the property when heated with it of changing its colour to a purple or blue. Mr. Charles Lauth, for example, in 1860, described the blue colour which was obtained from *azaleine* (nitrate of rosaniline) by means of protochloride of tin, aldehyde, the natural essences, etc.; and M. Kopp demonstrated that the same colour was produced from aniline red by means of wood spirit. But as none of these colours were permanent, they were disregarded. In 1861 MM. Girard and De Laire procured their imperial purple in the manner already mentioned, by heating equal weights of aniline and dry muriate of rosaniline, at a temperature of about 350° Fahr., for several hours. If the purple is wanted, the mass is merely treated with dilute muriatic acid until it loses its excess of aniline and aniline red, but if a pure blue is required, the acid treatment is continued until all the red tint is removed, and a pure blue remains. This is finally dissolved in acetic acid, or methylated spirit, and the blue dye, called *Bleu de Lyons*, is obtained. The same blue, but called *Bleu de Paris*, was procured by MM. Persoz, De Luynes, and Salvetat, by heating a mixture of aniline and dry bichloride of mercury in a sealed tube for 30 hours, at a temperature of 356° Fahr. The mass when cold is dissolved in boiling water, and the colour precipitated by means of common salt. This operation is repeated until the blue is quite free from the green pigment which accompanies it.

A blue, called *Bleu de Mulhouse*, may be obtained by the process patented by MM. Gros-Renaud and Schœffer in 1861, and which consists in boiling a solution of *azaleine* (nitrate of rosaniline) with gum lac and carbonate of soda for some time; and another blue named *azuline*, has been produced by M. Marnas by a like treatment of a substance called *peonine*, with eight times its weight of aniline; and the residuum is purified with a succession of solvents, as water acidulated with muriatic or sulphuric acid, then hot naphtha, then caustic alkali, and finally with water acidulated with muriatic acid. The azuline, or blue colour, which remains, is soluble in spirit and forms a rich blue dye. Blues are also produced by the action of numerous oxidizing agents on aniline or its salts, as by a solution of hypochlorous acid (Hofmann), by a solution of chlorate of potash and muriatic acid (Fritzsche), by peroxide of hydrogen (Lauth), by perchloride of iron or red prussiate of potash (Kopp), by peroxide of manganese or pernitrate of iron and hydrochloric acid (Scheurer-Kestner), by bichromate of potash and acid (Willm) and I have obtained it by oxidising the sulphate of aniline by means of the oxygen disengaged at the positive pole of a battery. In all these cases the blue is very difficult of solution, for it resists the action of every solvent but strong sulphuric acid. Taking advantage of this, Mr. Nicholson, in 1862, patented a process for purifying the blue colouring matter, by dissolving it in concentrated sulphuric acid, and then heating it for half an hour at a temperature of 302° Fahr. By diluting it with water it is precipitated in a modified condition, for it is now soluble in pure water. Dr. Hofmann ascertained that it was a substitution compound of rosaniline, in which three equivalents of hydrogen had been substituted by three equivalents of a hydrocarbon called phenyl ($C_{12}H_5$); he therefore named it tryphenylic-rosaniline, and this suggested the possibility of substituting other hydrocarbons, as methyl (C_2H_3), ethyl (C_4H_5), amyl ($C_{10}H_{11}$), etc., in which he was successful by acting upon rosaniline with the iodides of these radicals, and thus producing ethylic, methylic, and amylic substitution compounds of a rich blue and purple colour, called Hofmann's blues. Very recently the change has been effected by a more direct process without the aid of the iodide, but by heating a mixture of aniline, muriatic acid, and methylic alcohol under pressure, and then treating with iodine and chlorate of potash, or other oxidizing agent.

Aniline Greens.

Most of the blue substances just described become green by the action of acids, and again acquire a blue colour when they are washed or treated with alkalies. It has also been noticed that in certain states of oxidation, aniline acquires a green tint; but all attempts to utilise this colour failed, until, in 1860, Messrs. Calvert, Clift, and Lowe patented the process for producing it upon the fabric. Their process was to prepare the fabric with chlorate of potash, and then to print upon it with acid muriate of aniline. In a few hours a beautiful bright green colour, called *emeraldine*, gradually appeared, and it was fixed by merely washing it with water. If a blue tint were required, the fabric was passed through a solution of bichromate of potash, when the oxidation of the aniline was carried still further, and a dark indigo blue, called *azurine*, was produced.

A green colour may also be obtained by heating a mixture of two parts fuchsine with three parts strong sulphuric acid and one part water. When the solution of the fuchsine is complete, it is allowed to cool, and four parts of aldehyde are added. The mixture is again heated until it is a bright blue colour without a trace of violet. It is then treated with a boiling solution of hyposulphite of soda, and filtered. The residue upon the filter is to be boiled in water, and filtered while hot. After standing 24 hours it deposits a green precipitate.

Aniline Black.

Several processes have been proposed for making a black dye from aniline, as by acting on aniline with an oxide of chlorine, and then with a salt of copper; but the colour is not of sufficient importance to command attention.

Aniline Yellow,

called *chrysaniline*, or *phosphine*. This colour was first obtained by Mr. Nicholson, in 1861. He procured it from the residuum of rosaniline by the action of steam, whereby a dirty yellow solution was obtained. On adding nitric acid to the solution, the yellow dye was thrown down as a nitrate of little solubility, and by decomposing it with an alkali the base is set free, which either alone or in a form of a soluble salt communicates a rich yellow colour to silk and wool.

These are the principal colours obtained from aniline, and it may be of interest to examine the leading properties of these remarkable compounds. At first you will have remarked that the bases of nearly all the aniline colours are very insoluble in water, ether, and coal naphtha. They are more soluble in water acidulated with the mineral acids, and are still more soluble in acetic acid. Alcohol, however, is the great solvent for them. You will likewise observe that they are generally precipitated from their saline solutions by alkalies and by common salt, and in this manner they are generally purified. Tannin also produces an insoluble compound with them, and thus they are often fixed upon vegetable fabrics. They are endowed with great power of resistance, for they will bear the action of strong sulphuric acid without undergoing decomposition, but they cannot resist the action of powerful oxidizing agents, as chlorine, chloride of lime, or nitric acid. Reducing agents, as sulphide of ammonium and protosulphate of iron, destroy their colour; but the action is not permanent, for on exposure to the air oxygen is absorbed, and the colour reappears.

The bases themselves are not generally coloured, but they acquire their characteristic tints when they combine with acids. I have here the colourless, or nearly colourless, solutions of rosaniline, mauvine, and aniline blue, and you will remark that directly I expose them to the vapours of an acid (acetic) their characteristic tints appear.

The tinctorial power of these dyes is remarkably great. If, for example, I put a little Magenta, mauve, or aniline blue upon paper, and then shake off the powder as completely as possible, there yet remains sufficient to give deep tints when I blow a fine spray of alcohol and acetic acid upon the paper.

The affinity of animal substances, as silk, wool, feathers, horn, ivory, leather, etc., is so great that the dye instantly combines with them, and produces a permanent stain. The affinity, indeed, is so great that, as you will here see, a piece of flannel will completely absorb and remove the colouring matter from its solution in water. Vegetable tissues, however, have no such affinity for the colour, and therefore processes must be adopted for fixing the dye upon cotton and linen fabrics. One of these processes is to prepare the fabric with some animal substance, as albumen, serum of blood, the caseine of milk, or the gluten of wheaten flour. Advantage is also taken of the power which tannin has of combining with the colour and rendering it insoluble. The process of Messrs. Puller and Perkin is to soak the cotton tissue in a decoction of shumach, or other tannin material, for an hour or two, and then in a solution of stannate of soda for another hour; after which it is dipped into dilute sulphuric acid, and is then ready for the dye. By these contrivances the aniline colours are made fast upon all kinds of vegetable fabrics.

Starch appears to have the power of fixing the colours, for if shaken with weak solutions of them it will absorb the colour, and by falling to the bottom of the liquid leave the solution colourless.

The rationale of the change which takes place during the formation of the several colours is not altogether clear, although there can be no doubt that the essential part of it is the oxidation of aniline; for, as I have already stated, when a salt of aniline is exposed to the action of nascent oxygen set free from the positive pole of a galvanic battery, the characteristic tints of aniline are successively and quickly produced. At first there is bright yellow, then green, blue, violet, and lastly red, as if these were the successive phases of oxidation. The researches of Dr. Hofmann have demonstrated that all the aniline reds are salts of a well defined base, which he has named *rosaniline*; and the more recent inquiries of MM. de Laire, Girard, and Chapoteaut have shown that there are four such bases entering into the composition of coal-tar colours, as *violaniline*, *mauvaniline*, *rosaniline*, and *chrysotoluidine*, which form an arithmetical series advancing by successive additions of C_2H_2, thus:—

Violaniline	$C_{36}H_{15}N_3$
Mauvaniline	$C_{38}H_{17}N_3$
Rosaniline	$C_{40}H_{19}N_3$
Chrysotoluidine	$C_{42}H_{21}N_4$

Each of these bodies is produced in the same manner, by the oxidation and removal of 6 atoms of hydrogen from 3 atoms of aniline, or 3 atoms of toluidine, or 3 atoms of the mixed bases, thus:—

6 atoms of hydrogen from 3 atoms of aniline produce *violaniline*.

$$3\underbrace{(C_{12}H_7N)}_{\text{Aniline.}} + H_6 = \underbrace{C_{36}H_{15}N_3}_{\text{Violaniline.}}$$

6 atoms of hydrogen from 2 atoms of aniline and 1 of toluidine produce *mauvaniline*.

$$2\underbrace{(C_{12}H_7N)}_{\text{Aniline.}} + \underbrace{C_{14}H_9N}_{\text{Toluidine.}} - H_6 = \underbrace{C_{38}H_{17}N_3}_{\text{Mauvaniline.}}$$

6 atoms of hydrogen from 1 atom of aniline and 2 of toluidine produce *rosaniline*.

$$\underbrace{C_{12}H_7N}_{\text{Aniline.}} + 2\underbrace{(C_{14}H_9N)}_{\text{Toluidine.}} - H_6 = \underbrace{C_{40}H_{19}N_3}_{\text{Rosaniline.}}$$

and 6 atoms of hydrogen from 3 atoms of toluidine produce *chrysotoluidine*.

$$3\underbrace{(C_{14}H_9N)}_{\text{Toluidine.}} + H_6 = \underbrace{C_{42}H_{21}N_3}_{\text{Chrysotoluidine.}}$$

These colour bases are perfectly homologous in all respects, for they not only unite with acids to form salts which crystallise very freely, and which have remarkable tinctorial power, but they also contain within them three atoms of typic hydrogen, which may be replaced by certain radicals, as of the alcohols, etc.—methyl, ethyl, phenyl, etc.—forming derivative compounds of like basic properties, and frequently of high tinctorial quality.

The best known of these bases is *rosaniline*, which in its anhydrous condition is represented by the formula

$$C_{40}H_{19}N_3,$$

but which always contains two atoms of water in the hydrated state in which it is set free from its compounds, thus:—

$$C_{40}H_{19}N_3,2HO$$

It is readily obtained by decomposing its salts—the aniline reds—with an excess of alkali, soda, or ammonia, and in this state it falls as a dirty yellow or brownish-yellow precipitate; but by careful purification it occurs as a colourless base, which quickly becomes rose-red on exposure to any acid, even the carbonic acid of the atmosphere. It is nearly insoluble in water, slightly so in ammonia, and very soluble in alcohol, forming a deep red solution. Ether and coal-tar naphtha have no solvent action upon it. It combines with one, two, or three equivalents of acid to form salts which crystallize very readily, the first of them, the mono-acid salts, being remarkable for their lustrous metallic or bronze-like appearance and their beautiful rose-red solutions; these, indeed, are the true colouring compounds, the most important of which are the following:—

Fuchsine, or muriate of rosaniline	$C_{40}H_{19}N_3,HCl$
Azaleine or *Magenta*, the nitrate	$C_{40}H_{19}N_3,HNO_6$
Roseine, the acetate	$C_{40}H_{19}N_3,HC_4H_3O_4$

It was the last-named salt which composed the splendid bronze-like crystals of the crown which were exhibited in 1862 by Mr. Nicholson. And, besides these, there are sulphate, arseniate, oxalate, chromate, tannate, etc., of rosaniline. Most of them are freely soluble in water and in spirit, but the tannate is so insoluble in water that it is used for fixing the colour upon calico, and for recovering the dye from very weak solutions. To this end the otherwise waste products of aniline red are treated with a fresh infusion of nutgalls, and in a short time the rosaniline is precipitated in the form of a magnificent red lake of tannate of rosaniline, leaving the solution quite colourless. This lake is soluble in spirit and in acetic acid, and may be thus used for dyeing.

The salts of rosaniline with two equivalents of acid have not been studied, and even those with three of acid are not of any technical value.

Under the influence of reducing agents, as sulphide of ammonium, or the nascent hydrogen evolved from zinc when a solution of rosaniline in muriatic acid is left in contact with the metal, it is rapidly decolorized, and is transformed into a new base, which Dr. Hofmann has named *leucaniline*. This is effected by the absorption of two atoms of hydrogen, thus:—

$$\underbrace{C_{40}H_{19}N_3}_{\text{Rosaniline.}} + 2H = \underbrace{C_{40}H_{21}N_3}_{\text{Leucaniline.}}$$

The new base occurs in the form of colourless acicular crystals, which are scarcely at all soluble in water, but freely so in alcohol. The salts of it are also colourless, or dazzling white, although they re-acquire the red tint of rosaniline when their solutions are exposed to the action of oxidizing agents or even to the air.

Dr. Hofmann has ascertained that there is still another base derivable from, or closely related to, rosaniline—viz., *chrysaniline*. It is procured from the residual, or waste product of rosaniline, by the action of steam and nitric acid, as I have already described. It contains two atoms less of hydrogen than rosaniline, and therefore it stands in its relation to this base as rosaniline does to leucaniline, thus:—

Chrysaniline .... $C_{40}H_{17}N_3$
Rosaniline .... $C_{40}H_{19}N_3$
Leucaniline .... $C_{40}H_{21}N_3$

It is very soluble in water, and it forms yellow salts with acids, one of which, the nitrate, is a very soluble compound. The solutions of the base and of its salts communicate a splendid golden yellow colour to animal tissues.

Aniline blues are, for the most part, substitution compounds of aniline red, the three atoms of typic hydrogen being replaced by three of an organic radical. The blue, for example, which is produced by the action of aniline on a salt of rosaniline, is a compound in which the three atoms of hydrogen are replaced by three of phenyl, thus:—

Aniline red, or *Rosaniline*............ $C_{40}H_{19}N_3$
Aniline blue, Triphenylic rosaniline $C_{40}\left\{\begin{matrix} H_{16} \\ (C_{12}H_5)_3 \end{matrix}\right\}N_3$

And its production when aniline is heated with a salt of rosaniline is accompanied with the evolution of ammonia, disregarding the acid of the compound, thus:—

$$C_{40}H_{19}N_3 + 3C_{12}H_7N = C_{40}\left\{\begin{matrix} H_{16} \\ (C_{12}H_5)_3 \end{matrix}\right\}N_3 + 3NH_3$$

Other substitution compounds, in which the three atoms of hydrogen are replaced by three of methyl, ethyl, amyl, etc., have been produced by Dr. Hofmann by the action of the iodides of these radicals on the salts of rosaniline, or even by the more simple and direct process of heating them with the alcohols of the radicals under pressure. All these compounds are basic in their character, and they mostly form, with one equivalent of an acid, the blue colours which are known as Hofmann's blue and violet, and the violet of Paris.

The other bases of aniline and toluidine colours have not been so well studied, but it is very probable that the reactions and the general properties of *violaniline*, *mauvaniline*, and *chrysotoluidine*, are very similar to the preceding, and that they are capable of forming the like reduction and substitution bases.

ON THE ANALYSIS OF CAST IRON.

BY EDMUND G. TOSH, PH.D.

Before proceeding with the regular analysis of cast iron, I have examined some of the more important processes for the estimation of the numerous substances which make up its constitution. The analysis of cast iron is one of the more difficult operations of analytical chemistry, and to ensure accuracy many special precautions and much extra manipulation are necessary—not because the ingredients are of themselves difficult of determination, but because the quantity of iron in every case preponderates so largely over that of the other elements.

In comparing the merits of the various processes one specimen of iron was used throughout.

Estimation of Carbon.—The estimation of this element as it occurs in iron is a problem which has engaged the attention of many celebrated chemists. Connected with the literature of the subject we find the names of Berzelius, Karsten, Wöhler, Gay-Lussac, Regnault, Caron, and numerous others, but notwithstanding the labour which has been expended in this direction, we have not arrived at a method which does not necessitate a large amount of time and work for its satisfactory accomplishment.

a. Regnault's method,[*] with the modifications of Bromeis,[†] is thus carried out. About two inches of a combustion tube of hard Bohemian glass, closed at one end, are filled with a mixture of equal parts of chromate of lead and chlorate of potash. 3 grms. of the iron under examination, in a state of very fine division, are intimately incorporated with 50 grms. of a mixture of 40 parts of chromate of lead, and 6 parts of previously fused chlorate of potash, and introduced into the combustion tube, and lastly a layer of chromate of lead. To the tube a chloride of calcium and a Leibig's potash apparatus are attached; the former to retain traces of moisture, the latter to absorb the carbonic acid formed. The combustion tube is cautiously heated, first near the open end as in the conduction of organic analysis. When the mixture of the iron with the lead salt is brought to a dull red heat, the metal burns with incandescence, and the carbon is oxidised to carbonic acid, which is absorbed by the potash solution. At the close of the operation the mixture at the extreme end of the tube is heated, oxygen is evolved, all carbonic acid is driven forward, and the last traces of carbon consumed. From the increase of weight of the potash apparatus, due to carbonic acid, the amount of carbon may be calculated. In this way Regnault obtained very concordant results, which were afterwards confirmed by the experiments of Bromeis. I made two estimations by this process, and the results agree well with one another.

1. 3·240 grms. of iron gave 0·462 grm. CO_2 equal to 3·886 per cent. of carbon.
2. 3·8245 grms. of iron gave 0·5605 grm. CO_2 equal to 3·996 per cent. of carbon.

I have reason to think, however, that the percentage of carbon indicated, is somewhat too low in both cases, on account of loss of carbon during pulverisation of the iron. This loss, as pointed out by Morfit and Booth,[‡] is often appreciable, and in the case of highly graphitic iron very considerable. With this one exception the process is in every respect commendable, and where, as with spiegeleisen or white iron, this loss of carbon cannot take place, it strongly recommends itself. When instead of a mixture of chromate of lead and chlorate of potash, chromate of lead is used alone, no very reliable results can be obtained, and invariably the amount of carbon shown by this method is too small.

b. Fresenius's Method.[§]—A weighed portion of the metal, in borings or chippings, is dissolved in dilute sulphuric acid by the aid of heat. The gases evolved

[§] *Zeit. Anal. Chem.* iv. 69.

during solution, consisting mostly of hydrogen, are passed over red-hot oxide of copper. The gaseous hydrocarbons are burned, and the carbonic acid formed, after drying by chloride of calcium, is absorbed by potash solution in a Leibig's apparatus, and thus weighed. Fresenius states that in cases where the percentage of combined carbon is very low, this process may be used for its direct estimation. Where an estimation of the total carbon is required, the matter insoluble in the dilute sulphuric acid, remaining behind in the flask, is collected and burned in a stream of oxygen, and from the weight of the resulting carbonic acid, the amount of carbon may be deduced. This quantity, added to that obtained by burning the gases over oxyde of copper, gives the total quantity of carbon contained in the iron. In drying the insoluble residue previous to combustion in oxygen, an elevated temperature must be carefully avoided, as I have occasionally noticed that at a temperature of about 100° C., this insoluble matter gives off a strong-smelling, disagreeable vapour, in all probability a volatile hydrocarbon, formed by the contact of hydrogen and carbon in the nascent state. At a temperature of about 80° C. the odour evolved is very slight, and the loss inconsiderable, but the safest way is to dry over sulphuric acid. The presence of hydrocarbons in the graphitic residue, at once shows that this process could not be safely applied in the present case for the estimation of combined carbon directly. The following experiments illustrate the same point.

1. 1·42425 grms. iron dissolved in dilute sulphuric acid, and gases evolved passed over oxide of copper, gave 0·2525 grm. CO_2 = 0·4834 per cent. carbon.
2. 1·62425 grm. iron treated in the same manner gave 0·01625 grm. CO_2 = 0·2728 per cent. carbon.

The insoluble residues in both cases were collected and burned in oxygen.

From 1 gave 0.1964 grm. CO_2 = 3·7612 + 0·4834 = 4·2446 per cent. carbon.
From 2 gave 0·2319 grm. CO_2 = 3·894 + 0·2728 = 4·1168 per cent. carbon.

The deficiency in the amount of carbon in the gases in No. 2 is made up by the larger quantity in the insoluble matter.

This method requires a large amount of time for its execution, the apparatus is somewhat complicated, and the great number of operations which the carbon must go through render the exercise of extreme care more than usually necessary.

I would here remark, that in all my experiments I found the perfect combustion of graphite, even in oxygen, required a very high temperature. In my first trials, I sought to burn graphite at a dull red heat in a tube of hard Bohemian glass, but it remained almost unaffected in a stream of oxygen. I found it most convenient to place the graphite first in a platinum boat, insert this into a well-glazed porcelain tube, and expose to a full red heat in a small charcoal furnace. In a gentle stream of oxygen the carbon is perfectly burned in a few minutes, and the resulting carbonic acid is absorbed in the usual way by potash solution.

c. Wöhler's Chlorine Process.—This most excellent process is carried out in the following way. A weighed quantity of iron contained in a porcelain boat, is placed in a hard glass tube, and is exposed at a dull red heat, to the action of chlorine (first dried by passing over pumice stone saturated with sulphuric acid) till no more perchloride of iron is formed. The whole of the carbon remains in the boat, which, when cool, is transferred into a porcelain tube, and the carbon burned in oxygen as before described. An estimation by this method may be performed in two hours. Care must be taken to have the chlorine perfectly free from moisture, otherwise a portion of carbon may be lost by the formation of hydrocarbons. The results given by this process are very concordant, as the three experiments given beneath show.

1. 1·001 grms. of metal in borings gave 0·1595 grm. of carbonic acid = 4·348 per cent. of carbon.
2. 1·06775 grms. of metal gave 0·171 grm. CO_2 = 4·357 per cent. carbon.
3. 1·002 grms. of metal gave 0·159 grm. CO_2 = 4·327 per cent. carbon.

According to Max Buchner,* this process affords results as accurate as those obtained by Berzelius' chloride of copper method; and Professor Kerl of Clausthal states that in his laboratory it is employed almost exclusively.

d. Weyl's Galvanic Method.†—This very ingenious and beautiful method for the estimation of carbon is founded upon the fact that a piece of iron, attached to the positive pole of a galvanic battery, and suspended in hydrochloric acid, is dissolved, while the hydrogen is given off at the negative pole, dipping into the solution. Carbon and hydrogen do not thus come in contact in the nascent condition, and the formation of hydrocarbons, and consequent loss, is prevented. A recommendation of this method is that the iron does not require to be in powder.

A piece of iron 2 to 4 grammes in weight, attached to the positive pole of a Bunsen's cell, is suspended in dilute hydrochloric acid, just below the surface of the liquid. From the negative pole hydrogen passes off, while the iron dissolves quite quietly, and the strong solution of protochloride of iron formed may be seen falling in a regular steam through the lighter liquid. The iron is dissolved in about 24 hours, and the carbon is left behind in the same shape as the piece of metal from which it was derived.

In Weyl's earlier experiments it was found that some of the liberated carbon at the positive pole was carried over to the negative pole by the mechanical working of the stream. To prevent this, a diaphragm of bladder or parchment paper is interposed between the two, which entirely obviates the possibility of loss in this way.‡

Weyl recommends that the piece of iron should be suspended by means of platina pointed forceps, in such a manner that the acid does not reach the iron at its point of contact with the forceps, otherwise after the partial solution of the iron, the separated carbon intervening between the forcep points and the remaining piece of metal, would interrupt the galvanic current and the experiment would be lost. In my researches I used a small platinum sieve, kindly lent me by Professor Wöhler, in which I laid the pieces of iron, wholly immersed in the acid, and the action proceeded till the end as well as it did at the commencement. This interruption of the current is not, I think, to be feared, as both amorphous carbon and graphite are good conductors of electricity.

Schnitzler § when examining this process always found that a small quantity of hydrogen was given off

---

§ *Zeit. Anal. Chem.* b. iv. p. 78.

from the piece of iron during solution, and attributed this to the action of acid on small particles of metal which were unconnected with the main piece, distributed through the surrounding carbon, and beyond the influence of the galvanic stream. If we look upon carbon as a conductor of electricity this theory does not hold good. I noticed this evolution of gas in all my experiments, however dilute the acid. Immediately on dipping the piece of iron into the acid, gas bubbles formed on its surface, showing that the action had commenced, which, for my own part, I am inclined to attribute to a secondary and independent galvanic action between the iron and free carbon, either previously existing throughout the metal, or liberated the moment solution begins.

This evolved hydrogen possesses the characteristic odour due to the presence of hydrocarbons, always noticeable when cast iron is dissolved in acids under ordinary circumstances. As shown by Schnitzler, a loss of carbon consequently ensues, and my estimations lead to the same conclusion.

When no more hydrogen is given off at the negative electrode, showing that all the iron is dissolved, the carbon is collected in a small funnel stopped with asbestos, dried cautiously, transferred to a platinum boat, and burned in a stream of oxygen, and the resulting carbonic acid is absorbed in the ordinary way by potash solution. Subjoined are the results of two experiments:—

1. A piece of iron weighing 3·59125 grms. gave 0·5575 grm. CO_2=4·235 per cent. of carbon.
2. 2·04075 grms. of iron gave 0·30575 grm. CO_2=4·086 per cent. of carbon.

Weyl* has also proposed a second method for the solution of iron without the evolution of hydrogen, which consists in suspending a piece of the metal in dilute sulphuric acid, containing bichromate of potash dissolved. The carbon is unaffected, and when most of the iron is removed, the residue may be collected and burned in oxygen. I have made no estimation by this means.

Of these various methods I selected that of Wöhler for the determination of carbon in the specimens of iron I have examined, because while recording results of equal reliability with any, its performance requires much less time.

Arranged below in a tabular form are the amounts of carbon per cent., indicated by the various methods, in the same sample of iron.

	Carbon. Per cent.

NOTE ON THE CRYSTALLISATION AND THE SOLUBILITY OF PLUMBIC CHLORIDE.

BY J. CARTER BELL, F.C.S.

The various manuals and dictionaries of chemistry when speaking of plumbic chloride, fail to say anything on the phenomenon of its crystallisation; it is generally written that "it crystallises in brilliant needles.". This state of crystallisation only occurs under certain conditions, for if pure plumbic chloride be taken and dissolved in boiling distilled water, and then allowed to cool, the chloride does not crystallise out "in brilliant needles," but in a sort of cuneiform or arrow-shaped crystals, which are not white but of a delicate cream colour, and in the many experiments I have performed, I have failed in producing white brilliant needles by this method. But if the solution contains free hydrochloric acid, then we obtain white needle-shaped crystals; and according to the amount of HCl present in the mother liquor, so will the crystals vary in size, colour, and shape. With a small percentage of HCl, the crystals are white, and from 10 to 20 millimètres in length; if the HCl increases, very small white needles are obtained, and if it is strong HCl of 1·116 specific gravity, the crystals are no longer needle-shaped, but are of the form of the base of the right rhombic prism.

The Solubility of Plumbic Chloride.—A pure saturated solution of plumbic chloride at 16·5° Centigrade, contains ·9414 per cent. of the chloride, being the mean of three experiments; the addition of HCl diminishes the solubility considerably, and up to a certain point, which I have not yet determined, it may be stated that as the HCl increases the solubility decreases.

	Per-centage of $PbCl_2$
Water containing 1 per cent. of HCl (sp. gr. 1·116) at 16·5°C. only holds in solution	·3470

A saturated solution of plumbic chloride in hydrochloric acid of specific gravity 1·116 at 16·5°C., contains 2·566 per cent. of $PbCl_2$, but on the addition of water nearly the whole of the chloride is precipitated. These experiments seem to point that there must be a minimum hydrochloric solution of plumbic chloride, and also a maximum. Future experiments which I shall make will perhaps decide.

Manchester, July 29, 1867.

ON THE ACTION OF CHLORINE ON CARBONATE OF SILVER. PREPARATION OF CHLORATE OF SILVER.

BY PROFESSOR J. S. STAS.

If oxide or carbonate of silver suspended in water is diffused through an excess of saturated chlorine water, the silver is completely changed into chloride, as in the case of oxide and carbonate of mercury; and the water only contains besides the excess of chlorine pure hypochlorous acid, without a trace of chloric or perchloric acid. The chlorometric standard of the liquid, after the chlorine has acted on the carbonate, is almost identical with that of the chlorine water employed.

By passing a slow current of chlorine, *with constant agitation*, into water containing an excess of carbonate of silver in suspension, the first action is identical;

---

* *Pogg. Ann.* Bd. cxxvi. p. 617.

there are still produced chloride of silver and hypochlorous acid, but this hypochlorous acid only remains momentarily free, it slowly transforms another part of the carbonate into metallic hypochlorite. Indeed, if at the end of a short time the current of chlorine is interrupted, the agitation being continued all the time, the liquid loses the characteristic odour of hypochlorous acid, but preserves its energetic decolorising power because the hypochlorite of silver which is formed is very soluble in water.

Hypochlorite of silver, which to my knowledge has never before been described, is sufficiently stable in the presence of an excess of carbonate of silver, to remain undecomposed for several days; it is, on the contrary, very instable in the absence of this metallic oxide or carbonate. It has, indeed, appeared to me that so long as the solution of hypochlorite of silver is kept agitated with the carbonate the liquid preserves its transparency and decolorising power; if, on the contrary, it is left at rest, scarcely has the carbonate of silver settled when the limpid liquid becomes opalescent, and soon deposits large flakes of chloride of silver, which cover with a white coating the carbonate of silver at first deposited. The liquid at the same loses its decolorising power, and only contains chlorate of silver in solution, rendered alkaline by a small excess of carbonate dissolved.

According to what I have here shown, it is evident that the chlorate of silver by the action of chlorine on the carbonate, is the result of a secondary reaction of the hypochlorite of that metal which is previously formed. It would appear, moreover, as if all other chlorates were formed in a similar manner, but this is not the place to enter into this question.

The successive reactions may be represented by the following equations:—

$$12Cl + 3Ag_2O + 3H_2O = 6AgCl + 6HClO$$
$$6HClO + 3Ag_2O = 3H_2O + 6AgClO$$
$$6AgClO = 4AgCl + 2AgClO_3$$

I may say that argentic hypochlorite is very soluble in water; indeed, the clear liquid containing carbonate of silver suspended in it, and through which a slow current of chlorine has been passing for some hours, contains a considerable quantity of hypochlorite, which remains intact so long as it is in contact with the carbonate; but the excess of carbonate employed fixes on itself a large quantity of this hypochlorite, or, at all events, of the elements of this salt. The fixation of hypochlorite on this very slightly soluble argentic compound, results from two facts observed during the four times I have produced chlorate of silver by the action of chlorine on the carbonate and oxide. The first is the impossibility of washing these bodies after chlorine has acted on them for a certain time. Whatever care is taken, and however the washing is effected, the water always contains, besides the carbonate, a salt of silver containing chlorine and oxygen; the second fact is, that the carbonate on which chlorine has acted for a sufficient time to produce hypochlorite in solution, will still, after washing, furnish, under the influence of chlorine, a fresh quantity of hypochlorite, much more considerable than that which could result from the chlorine used in this second reaction. Observation has even proved that the greatest production of soluble hypochlorite takes place when two-thirds of the carbonate have been already submitted to the decomposing action of the chlorine.

Hypochlorite of silver is the sole silver salt that is formed by the action of chlorine on *an excess* of oxide or carbonate of silver suspended in the liquid and kept in a state of continual agitation. Spontaneous decomposition, or decomposition effected by the aid of heat, never produces the least trace of perchlorate when I have operated on a hypochlorite rendered slightly alkaline by an excess of carbonate in solution. During the passage of the chlorine, the hypochlorite which is formed may be destroyed again with formation of chloride of silver; but hypochlorous acid is still formed under these circumstances, and by reacting on a fresh quantity of carbonate of silver, a double quantity of hypochlorite is reproduced.

The conditions necessary to form chlorate of silver, according to the above observations, are therefore these:—A *slow* current of chlorine must react on the carbonate of silver (previously treated with chlorine to remove the alkali which it may contain) suspended in water and kept constantly in agitation until the chlorine has attacked the greater portion of the argentic compound employed; this agitation must be continued after the interruption of the current of chlorine, so as to change the free hypochlorous acid existing in the liquid into hypochlorite; the solution of argentic hypochlorite must be separated from the excess of the argentic compound employed in the first instance, so that the hypochlorite may change spontaneously into chloride and chlorate. The following is a description of the arrangement I adopted, so as to satisfy, as far as possible, the above conditions:—

Three kilogrammes and 935 grammes of nitrate of silver, free from foreign metals, were dissolved in twenty litres of distilled water; the solution was poured in small quantities at a time, into an equal volume of solution of carbonate of potassium prepared from pure cream of tartar. The carbonate of silver, which was voluminous, and of a very pale yellowish white, after having been kept for a long time suspended in an excess of solution of carbonate of potassium, was washed by decantation in the cold until no more potassium could be detected in the residue left by the washing water after evaporation to dryness. To arrive at this point I was obliged each time to violently shake up the carbonate of silver with water in a closed flask, as is done in a silver assay, to clarify the liquid. Taking these precautions, the washings lasted for fifteen days, repeating them several times a day.

The thin paste of carbonate of silver (which from its original yellowish white, had become of a beautiful yellow colour) was introduced into a flask of 45 litres capacity, covered with black cloth. This flask was fixed firmly in a frame attached to a kind of stirrup suspended above the ground by long cords. At each side, and at the foot of this stirrup, a string was fixed, and by alternately exerting a tractive movement by these strings, as strong an oscillatory movement as is desired could be communicated to the flask. To the neck of the flask was affixed a glass stopper pierced with two holes, one of which allowed the passage of a glass tube bent at right angles and leading the chlorine into the liquid, and the other admitted a glass tube, likewise bent, which allowed the escape of the carbonic anhydride set at liberty by the decomposition of the carbonate of silver. The tube by which chlorine was passed into the liquid was connected with a chlorine generating apparatus, by means of a vulcanised caoutchouc tube, long enough to permit free oscillation of the apparatus without exerting traction on the chlorine apparatus. The vulcanised caoutchouc tube had been boiled for an hour with a ten per cent. solution of hydrate of sodium to desulphurise it, and was then washed with pure water.

The apparatus being so arranged I allowed a *very slow* current of chlorine* to pass into the flask for an hour and a quarter, keeping it during the whole of this time in continuous movement. I then stopped the current of chlorine and continued to agitate the liquid so long as it exhaled the least odour of hypochlorous acid. The apparatus was then left at rest and the strongly coloured supernatant liquid was decanted. The carbonate of silver was then washed again by decantation, the first liquid decanted being added to the solution of hypochlorite already separated. The carbonate of silver was washed as long as it was possible to ascertain by aid of the spectroscope any traces of potassium in the residue left after evaporating the washing waters to dryness.

The solution of hypochlorite of silver, after having been preserved in darkness until it ceased to deposit chloride of silver, was evaporated to dryness; it left 31·819 grammes of a white saline residue.

The washed carbonate of silver, in the form of thin paste, was now introduced, with four litres of water, into the flask, and exposed for two hours to a current of chlorine, the agitation being incessant the whole time, and being kept up after the current of chlorine was stopped so long as the mixture smelt of hypochlorous acid. It furnished by decantation five litres of a strongly decolorising solution, which, left in darkness to spontaneous decomposition, yielded on evaporation 58·237 grammes of chlorate of silver.

The carbonate of silver was now washed for a third time. Already in the first washing water it was impossible for me to discover the least trace of potassium, by the aid of spectrum analysis, on examining the residue left by a whole litre of liquid.

I then diffused the carbonate of silver in a volume of water equal to that of the liquid decanted off, and for three hours exposed it to an uninterrupted current of chlorine with continual agitation. After the current of chlorine was stopped the mixture was kept in agitation for half-an-hour; after decantation the clear and colourless liquid did not emit the least odour of hypochlorous acid, but it had strong bleaching properties. On standing it deposited large quantities of chloride of silver, and on evaporation yielded 72 grammes of chlorate of silver.

Finally, the carbonate of silver, mixed with a considerable quantity of chloride of silver, was washed for a fourth time. Diffused through six litres of pure water it was exposed for six hours in the vibrating flask to a continuous current of chlorine. The hypochlorous acid having been changed into hypochlorite of silver by agitating the liquid with the remaining excess of carbonate of silver, I left the liquid to repose till all the hypochlorite was changed into chlorate and chloride. On evaporating the clear liquid with the usual precautions, I obtained in this operation 23 grammes of chlorate of silver.

I ceased acting with chlorine on the carbonate of silver because the salt was so whitened by admixture with chloride of silver that it was impossible by sight alone to distinguish whether any were present or not. Besides, when I stopped the operation the evaporation of all the liquids was not finished sufficiently for me to know how much chlorate was formed. On the supposition that the chlorine had acted to its fullest extent, I ought to have obtained 700 grammes of chlorate, but the total weight of the salt left on evaporating the four decanted liquids only came to 285 grammes. I had only produced two-fifths of the theoretical quantity, and it was therefore impossible to have obtained any perchlorate of silver.

The chlorates obtained in these operations were submitted to the following treatment:—

A portion of the 31·819 grammes obtained in the first operation having been examined in the spectroscope, was found to contain much chlorate of potassium. I did not therefore purify it.

The 58·237 grammes of chlorate from the second operation were dissolved in cold water. The solution was found to be faintly alkaline. Dilute chlorine water was added to it so as to cause the alkaline reaction to disappear, and it was then boiled in order to precipitate the traces of chloride of silver thereby produced. The perfectly neutral liquid was decanted and evaporated. Three separate crops of crystals were obtained from it. Each of these was separately reduced to the state of chloride by means of sulphurous anhydride.

A current of sulphurous anhydride precipitates sulphite of silver from a solution of chlorate, and the liquid contains chloric acid. This sulphite of silver only passes to the state of chloride by the consecutive action of sulphurous anhydride on chloric acid. During the passage of the gas there is, however, no way of telling whether the reduction of the chloric acid is partial or total, whether there is too little or an excess of sulphurous acid, and the amount of the excess. Another difficulty is occasioned by the relative slowness with which sulphurous acid reduces at 0°C. very dilute chloric acid; and, notwithstanding this, a low temperature and a great dilution of the liquid are indispensable conditions of success. I have, therefore, effected the reductions of chlorate of silver by means of a standard solution of sulphurous acid.

I now return to the three portions of chlorate of silver obtained from the 58·237 grammes of the second operation. The first portion containing the least soluble salts, still contained potassium, as shown by spectrum analysis. The second portion I lost in an attempt to reduce it in a current of sulphurous anhydride gas; the third part, weighing 23·932 grammes, was reduced by a standard solution of sulphurous acid at 0°C.

The 72 grammes of chlorate of silver produced in the third operation were dissolved in cold water. The solution was opalescent, and appreciably alkaline. I added carefully, dilute chlorine water till the alkaline reaction disappeared, then heated to precipitate the chloride of silver formed, and evaporated the decanted liquid over a water bath till a pellicle was formed. In order to obtain the chlorate in small crystals the liquid was cooled suddenly. The mother liquor was removed by aspiration. The chlorate was washed three times with ice cold water. After drying over sulphuric acid there remained 40·336 grammes of chlorate of silver, white and unalterable in the light. The washing waters and mother liquors yielded 27·581 grammes of salt equally white and unalterable in the light, but extraordinarily changeable by exposure to the air.

These 40·336 grammes of chlorate were added to the salt obtained from the 123·500 grammes yielded by the fourth operation. In order to free it from the perchlorate which, in spite of every precaution it

---

* The binoxide of manganese employed in the preparation of chlorine, after being finely powdered, was treated with dilute. boiling sulphuric acid so as to free it from the nitro-compounds which it always contains; it was then washed in pure water. This treatment is indispensable when chlorine is required absolutely free from chloride of azotyle.

might contain, I submitted it to the following treatment:—

It was dissolved in cold water, and the solution was mixed with dilute chlorine water until the very slight alkaline reaction which it at first possessed, had disappeared. The liquid was then boiled to precipitate the traces of chloride of silver thus produced. The clear liquid was then decanted, evaporated over a water-bath till a pellicle formed, and cooled quickly. The mother liquor was removed by aspiration, and the crystals washed with ice-cold water; all the washings except the first, were evaporared, till a pellicle formed, and the same treatment pursued in their case. After repeating the crystallisations, the washings, and evaporations, I succeeded in obtaining from the 123·5 grammes originally taken about 99 grammes of chlorate of silver, which I consider is as pure as can possibly be obtained. The mother liquors, which I carefully kept separated, yielded pure chlorate to the last trace. The preparation of chlorate of silver in the manner above described, I consider to be the most laborious and delicate operation which can be performed in analytical researches.

TECHNICAL EDUCATION.

The subject of Technical Education has recently attracted attention in this country, owing to the evidence considered to be afforded by the International Exhibition at Paris, of the inferior rate of progress recently made in manufacturing and mechanical industry in England, compared with that made in other European countries. It has been stated that this alleged inferiority is due in a great measure to the want of technical education, and steps have, therefore, been taken to ascertain from many eminent English jurors whether they agree with this opinion.

We have been favoured with an early correspondence which has taken place on this subject, and we think we shall be doing good service to the cause of education by laying an abstract of some of the letters before the readers of the Chemical News. The inquiry originated in a letter from Dr. Lyon Playfair to Lord Taunton, Chairman of the Schools Inquiry Commission. In it he states that, with very few exceptions, a singular accordance of opinion prevails that our country has shown little inventiveness, and made but little progress in the peaceful arts of industry since 1862. When he found some of our chief mechanical and civil engineers lamenting the want of progress in their industries, and pointing to the wonderful advances which other nations are making; when he found our chemical, and even textile, manufacturers uttering similar complaints, he naturally devoted attention to elicit their views as to the causes. So far as could be gathered by conversation, the one cause upon which there was most unanimity of conviction was that France, Prussia, Austria, Belgium, and Switzerland possess good systems of industrial education for the masters and managers of factories and workshops, and that England possesses none. A second cause was also generally, though not so universally admitted, that we had suffered from the want of cordiality between the employers of labour and workmen, engendered by the numerous strikes, and more particularly by that rule of many trades' unions, that men shall work upon an average ability, without giving free scope to the skill and ability which they may individually possess. Dumas asserts that technical education had given a great impulse to the industry of France. In going through the Exhibition, whenever anything excellent in French manufacture struck his attention, his invariable question was, "Was the manager of this establishment a pupil of the *Ecole Centrale des Arts et Manufactures?*" and in the great majority of cases he received a reply in the affirmative. General Morin, so well known as the director of the *Conservatoire des Arts et Metiers*, has lately sat on a commission to examine into the state of technical education in other countries, and to extend it in France, and their recommendations are likely to be promptly and largely acted upon. General Morin was of opinion that the best system for the technical education of *workmen* is to be found in Austria, though the higher instruction of masters and managers is better illustrated in France, Prussia, and Switzerland.

In 1853 Dr. Playfair published a little work on "Industrial Education on the Continent," in which he pointed out that as an inevitable result of the attention given to it abroad, and its neglect in England, other nations must advance in industry at a much greater rate than our own country. It is feared that this result is already attained for many of our staple industries, and the writer concludes his eloquently written letter by urging upon the Government to hold an official inquiry on this subject, and tell the people of England authoritatively what are the means by which the great States are attaining an intellectual pre-eminence among the industrial classes, and how they are making this to bear on the rapid progress of their national industries.

This letter was considered so important that copies of it were sent to a great number of eminent English jurors, with a request that they would communicate their views on the subject.

We extract from the numerous answers the following opinions, which more particularly bear on chemical and physical education:—

Professor Tyndall, F.R.S., expresses a general concurrence in the views of Dr. Playfair. The facilities for scientific education are far greater on the Continent than in England, and where such differences exist, England is sure to fall behind as regards those industries into which the scientific element enters.

He has long entertained the opinion, that in virtue of the better education provided by continental nations, England must one day—and that no distant one—find herself outstripped by those nations, both in the arts of peace and war. As sure as knowledge is power this must be the result.

Dr. Frankland, F.R.S., says that Dr. Playfair's communication substantially expresses his own convictions in regard to the matters therein mentioned. As a juror in class 44 of the present Paris Exhibition, he was not only forcibly struck by the want of evidence of progress in the different branches of chemical manufactures carried on in Great Britain, but still more so at the great advances made by other nations, more especially by Germany, France, and Switzerland, in respect of such manufactures since the year 1862, when, as a juror in the corresponding class, he had also an opportunity of comparing the chemical manufactures of different nations. He refers this want of progress in the manufactures of this country chiefly to the almost utter lack of a good preparatory education for those destined to take part in industrial pursuits. This great defect in the school and college education of England affects the masters and managers of our factories even more deeply than the workmen themselves. The former have but rarely had any opportunities of making themselves acquainted with the fundamental laws and principles of physics and chemistry; they therefore find themselves engaged in pursuits for which their previous education has afforded them no preparation, and hence their inability to originate inventions and improvements. It is true that such men not unfrequently imagine themselves inventors, and the yearly files of patent specifications abound with instances of their so-called inventions. The great loss of time and money attending these futile patents would be rendered impossible by a very moderate, if accurate, knowledge of chemical and physical science.

In the polytechnic schools of Germany and Switzerland the future manufacturer or manager is made familiar with those laws and applications of the great natural forces which must always form the basis of every intelligent and progressive industry. It seems that at length this superiority in previous training is more than counterbalancing the undoubted advantages which this country possesses in raw material.

DR. DAVID S. PRICE considers that as far as relates to chemical products, the exhibition made by Great Britain is a "deficient representation," and will not enable foreigners to form a correct estimate of the nature and extent of chemical manufactures now carried on in this country; what is shown in class 44 is, as a rule, injudiciously exhibited, contrasting painfuly with the taste and spirit evinced by the French in their arrangements in the same class.

The writer's conviction is that it is most important that these international competitions should not be allowed to degenerate into a means for advertising, and that it behoves those who are intrusted with their organisation to see that the several departments of industry are intrusted to men who take an active interest in them, and are thus a guarantee that every endeavour will be made to have them fairly and properly represented, which is not the case on the present occasion, so far at least as refers to classes 40 and 44.

He does not agree with Dr. Playfair that the technical education of working men is the most important method for the maintenance of our industrial supremacy. The information gleaned by acting upon his suggestion would be instructive, and great good would result from its application; but what is really wanted for this country, and is of vital consequence to our future prosperity, is a higher scientific culture of those who are likely, in the natural course of events, to be master manufacturers, so that when discoveries are made they may fructify and not stagnate or decay, as has too often been the case, for want of intelligence on the part of those who command capital and works to perceive their merits; and that they, the manufacturers, may be able to appreciate and adequately remunerate the scientific talent that this country is, and always will be, able to afford them. No reformation bearing upon industrial progress is more required than in the Legislature, and it is a reproach to the country that science is not represented in Parliament.

It would be well if an investigation were made as to what have been the results of the teachings in science of the German universities; what Liebig has done for modern chemistry, and how the system inaugurated by him at the small University of Giessen has spread throughout the world, and what benefits have resulted from it; what we owe to the teachings of other chemists, the physicists, metallurgists, and geologists of those excellent seats of learning. Whilst advocating the necessity for the dissemination of scientific training in England, Dr. Price does not omit to bestow a passing tribute of commendation to the success of those institutions of recent date which were established to supply a want that existed many years since;—the Royal College of Chemistry, of which the late Prince Consort was the President, the School of Mines, and the colleges in the metropolis where scientific departments have been founded. In the first named, many of the men who have taught, and not a few of those who have studied there, have not only enriched chemical science by their researches, but have left a permanent mark upon the leading industries of this country. From the School of Mines have emanated men who in metallurgy and geology have greatly extended the application of those sciences. It is, however, a well-known fact that the public do not rightly appreciate the education that this institution is capable of affording, and that comparatively but few of the sons of manufacturers avail themselves of its advantages.

The writer calls particular attention to a plan proposed by the eminent chemist, Frémy, that young chemists of talent, who are desirous of devoting their time to the advancement of science, and therefore for the benefit of mankind, should be liberally supported by the State. It is suggested that this excellent idea should be brought to the notice of the Chancellor of the University of London, who from his well-known zeal in the cause of education, and from his position, is better able than any one else to obtain the evidence of scientific men as to its value, and, if approved of, to secure its adoption in this country. The same principle might well be extended to the other departments of science which bear upon industrial progress.

The author's firm belief is that extended scientific education is of the highest consequence to us if we wish to retain our present position in the scale of nations; that it will mostly benefit the future master manufacturer, that it must tend to elevate the social position of the intelligent working man, and to create a greater sympathy between master and man than at present prevails, and if it do this, the evils which threaten to impede, if not to paralyse our national progress, may be averted.

JAMES YOUNG, Chemical Works, Bathgate, feels bound to say that his experience accords with that of Dr. Lyon Playfair. So formidable did the rate of progress of other nations appear to many, that several meetings of jurors, exhibitors, and others took place at the Louvre Hotel on the subject. The universal impression at these meetings was that the rate of progress of foreign nations in the larger number of our staple industries was much greater than our own. But it must be stated that a large number of our first-class machine and other manufacturers are not exhibitors in Paris, whereas other nations, he believes, have taken care to bring forward their very best; still, the great progress of other countries is evident. The reason for this increased rate of progress is the excellent system of technical education given to the masters of workshops, sub-managers, foremen, and even workmen.

England for a long time excelled all other countries in the finish of her machines; but now we find that foreign machine makers are rapidly approaching us in finish, and, having skilled and intelligent labour cheaper than ourselves, are progressing in all the elements of manufacturing.

The writer uses his own case as an illustration. Originally he was a working man, but he has succeeded in increasing the range of manufacturing industry. The foundation of his success consisted in his having been fortunately attached to the laboratory of the Andersonian University in Glasgow, when he learned chemistry under Graham, and natural philosophy and other subjects under the respective professors. This knowledge gave him the power of improving the chemical manufactures into which he afterwards passed as a servant, and ultimately led to his being the founder of a new branch of industry, and owner of the largest chemical manufacturing works of the kingdom. It would be most ungrateful of him if he did not recognize the importance of scientific and technical education in improving and advancing manufactures. Many men without such education have made inventions and improvements, but they have struggled against enormous difficulties, which only a powerful genius could overcome, and they have been sensible of the obstacles to their progress. Stephenson, who so greatly improved locomotives, had to be his own instructor, but he sent his son Robert to Edinburgh University, and the son did works at least as great as the father, and with far less difficulty to himself.

The improvement in locomotion has necessarily created great competition in the industries of the world; and unless we add skilled instruction to manual labour, England cannot expect to maintain her position in the industrial race.

ON THE PRACTICAL LOSSES OF SULPHUR Etc., IN THE VITRIOL MANUFACTURE.

BY CHARLES R. A. WRIGHT, B.SC.

The main causes of the great differences often visible between the amount of sulphuric acid theoretically obtainable from a given quantity of sulphur, and that practically obtained, seem to be three in number, viz.:—

(1). Loss of SO_2 by leakage from burners, pipes, chambers, etc.

(2). Incomplete combustion of all the sulphur used.

(3). Non-conversion of all SO_2 formed into SO_4H_2 and consequent loss of SO_2 by its passage as such into the chimney.

(I.) The prevention of the first source of loss is a mere mechanical matter; without great care on the part of the workmen a considerable amount of sulphurous gas may escape from the kilns during the process of recharging, etc.; inattention to the speedy repair of all leaks in brickwork, pipes, tunnels, etc., may also cause a considerable amount of loss.

Notwithstanding the manifest bad policy of such a course, it is not uncommon to find a manufacturer neglecting to stop a chamber for repairs until the escape of gases by leakage has almost completely corroded the wooden framework of the chamber. The writer has seen a chamber, when stopped at last, present, to an observer inside, the appearance of a star-spangled sky, owing to the large number of small holes and leaks; in such an instance as this, the loss of time in stopping earlier for repairs and the expense, would have been many times repaid by the saving of sulphur lost by leakage, not to speak of the prevention of damage to the framework of the chamber and to surrounding objects by corrosion. Not only is sulphur thus lost by leakage and diffusion, but excess of air is often drawn into the chamber through the holes, thus practically diminishing the size of the chamber, and still further reducing the yield. It may be noticed here that want of attention on the part of the plumbers in first building the chamber, in so attaching the strap as to distribute the weight of the lead equally, is a frequent cause of small holes and leaks; the leaden sheet is apt to become torn where the strap is attached if too great a strain be upon it, and even if not torn the lead is strained, becomes thinner, and is more readily perforated by the action of the contained gases. The quality of the lead used, too, is of great importance; it is a false economy to buy cheap sheet lead, as it is almost certain to wear unequally, and last a much shorter time than a really good well manufactured article.

Some manufacturers consider it more profitable, in the long run, to pull down a chamber after working four, five, or six years, to melt up the lead, and rebuild with fresh materials, giving extensive repairs to the foundations, framework, kilns, etc., wherever necessary; calculating that the loss of time and capital in thus rebuilding is no more than what would have been necessary for repairs alone had the chamber been kept at work a few years longer; whilst the prevention of damage by leakage and the saving of sulphur render a handsome return for the outlay; others, again, prefer to work a chamber for eight, nine, ten years almost uninterruptedly; in fact for as long as it can by any artifice be made to hold gases.

The following numbers, being the results of successive years' working with a series of chambers to which but little repairs were allowed during the whole time, illustrate the enhanced loss from the increasing leakage:—

	Nitre used per 100 parts of sulphur burnt.	Cubic mètres of chamber space per kilogramme of sulphur burnt per diem.	Practical yield. Theoretical=100.
1st year ..	9·31	1·150	81·5
2nd " ..	9·84	1·073	75·4
3rd " ..	10·02	1·017	68·4

It is here manifest that while the sulphur burnt has increased a little, there is a very great falling off in the yield, notwithstanding that the proportion of nitre used is progressively greater; the total amounts lost in the three periods are respectively 18·5, 24·6, and 31·6.

(II.) The loss of sulphur from incomplete combustion in the burners is only noticeable to any great extent where pyrites is used. It is almost impossible to burn on the large scale any pyrites so that the burnt residue shall not contain at least 2·5 to 3·0 per cent of sulphur; where slaty pyrites containing about 30—35 per cent. of sulphur (such as Wicklow sulphur ore) is used, the residue will probably retain 3·5 to 4·0 as a minimum,* and as this burnt pyrites amounts in weight to about 80 per cent. of the green pyrites used, about 8 to 10 parts out of 100 of original sulphur will remain unburnt as a minimum.

When richer ores (such as Huelva) containing 48—50 per cent. of sulphur are employed, the residue may contain 3 per cent. of sulphur when fairly burnt, and will amount to about 67 per cent. of the weight of green ore used; so that about four parts in the hundred of original sulphur remain unburnt. Sulphur may also be volatilized as such, condensing in the pipes, or being

---

* With a hard slaty ore, 4 per cent. of sulphur is probably below the mark for an average on the large scale; the writer has repeatedly seen heaps of hundreds of tons of such ore, carefully burnt, and yet retaining an average of 5 or 6 per cent. of sulphur.

carried over into the chambers: this probably is entirely preventable by paying due attention to the temperature of the kilns, supply of air, etc.

(III.) The loss of sulphur from incomplete conversion of SO_2 into SO_4H_2 may be due to several minor causes, such as the introduction of too little steam, or too much air; the use of an insufficient quantity of nitre; or what is, perhaps, most frequently the case, the allowance of too little chamber space in proportion to the amount of sulphur burnt.

Each manufacturer has a different standard as to the proportion of nitre which should be allowed to a given amount of sulphur; more nitre is required when pyrites is used than where sulphur is burnt, to overcome the dilution of the gases by the nitrogen of the air used to oxidise the iron, etc., contained in the pyrites; more nitre is again required when more sulphur is consumed to a given amount of chamber space. (*Vide* numbers previously given.) The following numbers indicate the average amounts of nitre used by different manufacturers, who have kindly furnished the writer with information on this point:—

Material burnt.	Nitre per 100 parts of sulphur consumed.
Pyrites containing 45—50 per cent. of sulphur	8·5
" " 30—50 " "	12·0
" " ditto " "	10·0
" averaging 35 " "	12·5
Sulphur	10·0

N.B. In none of these instances were Gay Lussac's nitre towers employed. For comparison, the following numbers are quoted from Richardson and Watts's *Technological Dictionary*, Vol. 1., Part iii., second edition:—

		Nitre per 100 parts of sulphur used.
Page 71	Sulphur	5·0
317	ditto (Payen, Marseilles)	6·0
318	ditto (Jarrow Chemical Co.)	8·9
317	Irish pyrites (assumed to contain 30 per cent. of sulphur, Gossage)	13·3

Again, each manufacturer has a different opinion as to the proportion to be observed between the chamber space and the amount of sulphur burnt. Thus the numbers given as an average in R. and W.'s *T. D.*, p. 80, correspond to 1·672 cubic mètre per kilogramme of sulphur burnt daily; in "Muspratt's Dictionary," *Art. Sulphuric Acid*, the numbers given as in a Lancashire works represent about 1·35 cubic mètre per kilogramme, whilst the numbers given before show that less space than this is often allowed. With reference to this point, it may be observed that, as a general rule, it is more profitable to sacrifice a small portion of the theoretical yield (*i. e.*, to cause the amount lost to be greater) in order to produce a greater quantity of a manufactured article, than it is to lessen the amount produced in order to gain the maximum yield possible. Some manufacturers indeed say it is better to strain everything to the utmost, to produce the maximum *quantity*; of course, however, there is a limit beyond which it is unwise to go, as the increased wear and tear and damage to *quality*, together with the diminished yield, may render this course the least paying.

It is difficult to give more than a rough estimate of the amount of loss which is practically wholly unavoidable. With Huelva pyrites, the results obtained with a large series of chambers furnished with coke towers, but not with Gay Lussac's denitrating apparatus, showed that it is perfectly possible to obtain 82—84 parts of sulphur in the form of acid of specific gravity 1·700 from 100 parts of sulphur used as pyrites; the nitre used being about 10 parts for every 110 of sulphur used; and from 1·100 to 1·200 cubic mètre of chamber space being allowed to every kilogramme of sulphur burnt daily. Of the 16—18 per cent. of this *total loss* from 4 to 5 per cent. were due to the sulphur left unburnt in the pyrites, and consequently about 12—13 per cent. to other causes—viz., leakage, non-conversion of SO_2 into SO_4H_2 etc., etc.

"A Practical Chemist" writes to the Chemical News of July 13, 1866, that he obtains from a ton of Irish ore, at 30 per cent. of sulphur from 18 cwt. 1 qr. 5 lbs., to 18 cwt. 2 qr. 0 lb. of acid of specific gravity 1·75. Acid of this strength at 15°C. contains 81·45 per cent. of SO_4H_2 (Bineau). Hence his total loss is from 18·0 to 18·9 parts out of 100 of original sulphur, of which probably eight or nine parts are due to the unburnt sulphur in the pyrites.

Payen obtained from 1,600 kilogrammes of pure sulphur 4,280 of acid of specfic gravity 1·85 (*i. e.*, of SO_4H_2). [Richardson and Watts's *Technological Dictionary*, I. iii. 317.] Hence his total loss was 12·7 parts in 100.

It would appear, therefore, that whether pure sulphur, rich pyrites containing 48—50 per cent. of sulphur, or poor pyrites at about 30 per cent. are employed, from 10 to 13 parts of sulphur out of 100 employed are lost by causes other than the non-conversion into SO_2 of all the sulphur used. This probably represents about the minimum practical loss on the large scale; as noticed before, by bad repair of chambers, etc., etc., this loss is greatly enhanced.

FOREIGN SCIENCE.

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Your correspondent is so profoundly impressed with the vulgarity of enthusiasm, that he has endeavoured to the very utmost to suppress any traces of that objectionable sentiment in his letters. In fact, it is very difficult to be guilty of the fault alluded to after spending a week in the Exposition. Gazing at works of science or art for a long time, especially if one is to write about them, produces a state of mind in which an almost stupid tranquillity is a prominent feature, and your correspondent verily believes that the "dignified repose" which the world admires in some of its idols, is often so nearly allied to stupid tranquillity, and is so difficult to distinguish from it, that it may be said to be merely an isomeric modification. The poor worn-out Frenchman who complained so bitterly that he had had "beaucoup de Sultan," told me in confidence that the air of dignified repose which so eminently distinguishes Abdul Aziz when inspecting the greatest triumphs of science, was in fact the stupid tranquillity of ignorance. He also informed me that the predecessor of Abdul-Aziz (Abdul-as-was ?) generally enjoyed the same enviable state of mind. Certain it is, that the only thing in the building that caused a smile of intelligence to pass over the Sultan's face, was a punching machine in full work, and when he was told by his interpreter that it was capable of administering 1,000 punches a minute, he replied with decided animation, that he would take one home for the benefit of the heads of those who had persuaded him to leave Turkey. Let us hope that the fatigues to which you will subject that unhappy potentate in England, will make him forget his severe (although just) determination. To return to our work:—

Your correspondent examined with great interest the two cases of Messrs. Calvert and Lowe. They are described in the English catalogue as follows:—

14. Calvert, F. Crace and Co., Gibbons Street, Bradford, near Manchester. Carbolic acid, etc. 60. Lowe, Charles and Co., 14, Fountain Street, Manchester. Carbolic acid and its derivatives, etc.

The chemist who would follow the history of carbolic acid would have to pass in review one of the most interesting phases in the whole of organic chemistry. Discovered in 1834 by Runge, it forms one of the vast number of intensely interesting substances presented by that remarkable man to science as mines of wealth to be explored step by step, and more and more minutely, as methods of investigation were perfected. It is, in fact, one of those products of destructive distillation, whose history, which reads like a romance, has been developed by the labours of nearly all the greatest names associated with organic chemistry—Runge, Laurent, Gerhardt, Wöhler, Kopp, Hofmann, Williamson, Kolbe, Cahours, Erdmann, Fritzsche, Piria, Liebig, Dumas—all these names are found at the head of the memoirs in which are developed step by step the history of carbolic acid.

Carbolic acid, known also as phenol, phenic acid, hydrate of phenyl, phenylic alchohol, and coal tar creosote, has the formula $\Theta_6H_6\Theta$, and may be represented as water in which one atom of hydrogen is replaced by the radical phenyl. It is produced in a state of considerable purity by distilling salicylic acid; the carbolic acid from this source has, however, been asserted, too hastily, to be only isomeric with the coal-tar substance.

The fact is, that until very lately, chemists had no opportunity of working with carbolic acid of perfect purity. This has led to many incorrect ideas regarding it; for example, one of the differences between the carbolic acid from coal tar and that from salicylic acid, has been said to be the greater rapidity with which the crystals from the former source liquefy when exposed to the air, but, when perfectly pure, crystals of the coal-tar acid may be exposed without deliquescing for months together.

It is remarkable, moreover, to find that the substance whose properties we are discussing, is one of those which, as far as purification goes, has been grappled with more successfully in the manufactory than in the laboratory. The most severe test for the purity of carbolic acid, like that of most crystalline organic substances, is its melting point. According to Gerhardt this is between 34° and 35° (*Chimie Organique*, iii. 16.) But crystalline carbolic acid can now be obtained in commerce, of which the melting point is as high as 42°, or even a little higher. On the other hand, the boiling point of this pure acid is given by Mr. Lowe as 182° thermometer, in liquid, or 178°·8 thermometer in the vapour, the atmospheric pressure being 743·19 mm. (29·26 inches), whereas Laurent gives 187°—188°, and Scrugham, who worked on the subject in the laboratory, and under the eye of Williamson, gives 184°. From this we conclude that pure carbolic acid has a much higher melting point, and a somewhat lower boiling point than has been ascribed to it hitherto.

Messrs. C. Lowe and Co. exhibit a large mass of absolutely pure carbolic acid, weighing no less than two cwt., having the melting and boiling points given above. It is proper to mention that Dr. Crace Calvert, who is fully cognisant of all the facts recently discovered relating to carbolic acid and its congeners, gives 187° as the boiling point of carbolic acid* agreeing nearly with the determination of Laurent.

The firm of F. C. Calvert and Co. were the first to manufacture carbolic acid in a comparatively pure condition; it then consisted in a colourless fluid yielding crystals at 15°. This was in 1859. In 1861 they succeeded in obtaining it in colourless detached crystals, fusing at about 25°. Two years later the manufacture was so far improved that the melting point of their best acid was raised to 34°, the number given by Gerhardt. At the end of 1864 they succeeded in removing the sulphur compounds which adhere with such tenacity to the acid products of coal tar, and thus rendered the carbolic acid fit for medicinal purposes. It was not until 1866, however, that the absolutely pure acid was isolated with a melting point between 41° and 42°. Other manufacturers do not appear to be aware of the processes employed by Messrs. Calvert and Lowe, for they do not exhibit in their cases acid of a higher melting point than about 25°.

Messrs. Lowe and Co. state that absolutely pure carbolic acid *does* slowly become coloured by exposure to light, and that when this coloration is not observed, it arises from the protective influence of certain impurities, apparently sulphur compounds.

Messrs. Calvert and Co. also exhibit their disinfecting powder, salve for foot rot in sheep, and sheep dip, also picric acid and aurine, and, finally, rosolic acid.

Messrs. Lowe also exhibit picric acid, prepared by the action of nitric acid on sulpho-phenic acid, a process which is said to have several advantages, particularly as regards the quantity of the resulting product. They also show rosolic acid and a fine lake prepared from it for the use of paper-stainers. In addition to the above they have in their case picramic acid prepared by reducing picric acid with an alkaline sulphide. It is used in commerce for dyeing browns.

Messrs. Lowe's case contains a series of specimens which almost exactly represent the various epochs of the improvements in the manufacture of carbolic acid, alluded to above. They consist of the various commercial qualities, having the following melting points:—

Crude carbolic acid, fluid at ordinary temperatures.

Purified	do.	"	melting	at	15°
"	"	"	"	"	29
"	"	"	"	"	35
Pure	"	"	"	"	42·25

They also exhibit what they and Dr. Calvert insist on calling bi-hydrate of phenyl. This substance is simply carbolic acid, with water of crystallisation. Dr. Calvert's formula (C = 6) is

$$C_{12}H_5O.2HO.$$

But as the water of crystallisation is given off on the application of heat, it is obvious that the true formula is:—

$$(C = 6) \quad 2C_{12}H_6O_2.2HO, \text{ or:—}$$
$$(\Theta = 12) \quad 2\Theta_6H_6\Theta.{}_2H\Theta.$$

It gives your correspondent much pleasure to admit the gratification he derived from the examination of the cases of Messrs. Calvert and Co., and Messrs. C. Lowe and Co. Messrs. Calvert and Co.'s case would, however, have appeared to much greater advantage if the globes containing the specimens had not been covered to such an extent by loose paper advertisements, which to a great extent hide the contents.

Messrs. Calvert and Co. have obtained a silver, and Messrs. Lowe and Co. a bronze medal.

Fatigued with wandering from case to case to make comparisons between English and foreign manufacturers (for, owing to the perhaps inevitable distance between them, your correspondent at times has had to walk miles in this way), it was a relief to come at last to a case where attempts at comparison would have been useless. I allude to the, in many respects, unrivalled display of Messrs. Howard and Sons, of Stratford. Their name has for many years held an enviable position with regard to the purity and beauty of their chemicals, and the contents of their case fully sustain their old reputation. In the English catalogue they are described thus:—"48. Howard's and Sons, Stratford, near London, salts of quinine, and other chemicals."

Among the many remedial agents which organic chemistry has afforded us, quinine occupies the first place, chloroform the second. Without quinine, large tracts, indeed whole countries, would be simply uninhabitable for Euro-

---

* Chem. Soc. J., xviii. 66.

peans. To the backwoodsman a supply of quinine is as important as gunpowder. The "quinine famine" in the Mauritius demonstrated to thousands how small a thing even gold itself might become in comparison with the life-saving salt.

If the search for artificial quinine has been as unsuccessful as that for the Philosopher's Stone, it has at least resulted also in some great discoveries. It does not appear to be generally known that the first of the aniline colours was discovered during the search for artificial quinine! But, tired of waiting for that which did not come, finding that chemists could not produce quinine, it struck certain minds that it would be a surer plan to assist Nature a little, and Nature, as she always does when properly called upon, responded liberally. In effect, owing to the wasteful and ignorant manner in which bark was collected in its old habitat, it was, especially in the finer and richer varieties getting scarcer, this circumstance has induced certain enterprising men to cause the cinchonas to be introduced into India, and it has not only been found that the change of habitat does not prevent the development of quinine, but the valuable discovery has been made by McIvor, and confirmed by De Vrij, that covering the bark during its growth with moss increases the percentage of alkaloïds. The cinchona plantations in India are now so flourishing that there need be no apprehension of the supply of quinine ever failing, and if the discovery of artificial quinine should ever now be made, it would have to depend upon its value for its cheapness. We are aware that the discovery of artificial quinine has more than once been announced, but up to the present time such announcements have never been supported by positive evidence.

Messrs. Howards show an unrivalled collection of barks, including several from the new Indian plantations, and a specimen grown in England by Mr. J. E. Howard. It is exceedingly interesting to find that this English bark also contained quinine, for a specimen of the alkaloid extracted from it and its sulphate are exhibted. In addition to the above, this remarkable case contains specimens of the following alkaloids or their sulphates:—

Quinine	$C_{20}H_{24}N_2O_2$
Quinidine	$C_{20}H_{24}N_2O_2$
Cinchonine	$C_{23}H_{24}N_2O$
Cinchonidine	$C_{20}H_{24}N_2O$
Aricine	$C_{23}H_{26}N_2O_4$

It appears to your correspondent that an attempt to convert quinidine, cinchonine, or cinchonidine into quinine would be far more likely to meet with success than any efforts to produce that alkaloid by building it up step by step, and considering the enormous quantities of cinchonine which have been accumulated by quinine manufacturers, and are almost valueless, it is evident that such a discovery, however hopeless it may look at present, is well worth an effort. It must not be forgotten moreover, that researches of this kind, if carried on by competent persons, are certain to be fruitful in discoveries; even if the great end sought for be not attained. The admirable experiments of Pasteur are quite enough to prove the truth of this assertion.

In addition to the above, Messrs. Howard exhibit numerous chemicals of the highest possible quality. Amongst them is benzoic acid, on the perfect purity of which they pride themselves. It is free from the slightest admixture of the hippuro-benzoic acid, made by boiling hippuric acid (from the urine of cattle) with hydrochloric acid. This artificial benzoic acid is largely imported from the continent and sold as the genuine article. The acid thus produced is, however, never quite free from the odour of the urine of herbivorous animals, and, no matter how carefully purified, is without the fragrance which characterises it as obtained by sublimation from gum benzoin. This has induced some unscrupulous persons to mix a portion of the acid from benzoin with that from urine, in order that the fragrance of the one may carry the other off.

The tartaric and citric acids exhibited by this firm are in superb crystals, and have the appearance of being in the highest possible state of purity.

A curiosity in its way is carbonate of ammonium, prepared entirely from volcanic products, and therefore free from the impurities of which traces are almost always to be found in the salt as obtained from the crude sulphate of ammonia of the tar distilleries. As is well known, crude boracic acid from Tuscany often contains borate, sulphate, and chloride of ammonium. One sample analysed by Wittstein, contained no less than eight-and-a-half per cent. of sulphate of ammonium. The carbonate of ammonium shown by the Messrs. Howard, is obtained in their process for preparing borax from the crude boracic acid of commerce, and is, therefore, as they say, of purely volcanic origin. We believe there is no other firm who prepare salts of ammonium from the same source. The morphia and its salts shown in the same case, appear of very fine quality, and the same remark may be made with regard to their mercurial preparations. I am much pleased to see that the admirable display I have described, has obtained the distinction of a gold medal.

It is becoming common now to hear people express the wish that the present Exhibition will be the last for many years to come. But, as is so often the case in other matters, the majority of the persons who talk thus have really no definite reason for what they say. When you ask them for a motive for expressing their objection to exhibitions, you generally get such vague and unsubstantial reasons as "Oh, they are such a bore, you know." "They don't really do any good," or "They injure the retail trade of the cities where they are held." "One is sick of exhibitions," and so on. Now, while your correspondent has never once heard a really sound argument against exhibitions, he has, on repeated occasions, seen and heard enough to show him that the present Paris Exhibition must (if we do not allow our insular vanity to cause us to fall into decadence), exercise a most important influence upon our arts and manufactures.

I contend that no Englishmen of sound judgment could possibly examine in detail, as your correspondent has done, the various departments allotted to the European kingdoms, without having the fact forced upon him that our neighbours are running abreast of us in a race which, if we lose, will disgrace us for ever.

The intense dislike which a vast number of influential people took to all the schemes of the late Prince Consort, led them to oppose everything connected with his attempts to encourage technical education. But, if we are to retain our supremacy—nay, if we are not to be ignominiously beaten in the very departments where we have somewhat too superciliously fancied ourselves invincible, we must not only soundly educate our workmen in all the subjects relating to their special avocations, but we must also *stimulate their ambition.*

Fortunately the minds of some of the most active and far-seeing of our scientific and political men are directed to this deeply important question, and your correspondent trusts that you, Mr. Editor, will keep the matter before the scientific public.

To chemists the matter is as important as to engineers and artists. The chemical manufactories of France and Germany, especially the latter, are always able to obtain the services of men who, having received their chemical education in laboratories directed by high-class men, are able to devise new processes, improve those already existing, and, especially to adopt, simplify, and cheapen methods invented in this country, so as to deluge our markets with low-priced and often good articles, to the serious injury and even ruin of our own manufacturers.

Of all the faults which tend to the perpetuation of the system, or rather want of system, under which we are now obstinately insisting on learning how to be beaten, the greatest is the stupid vanity which leads us to underrate the strength and, above all, the intelligence of our rivals. We know how ruinous this is in war; it is equally so in the conflict between English and foreign manufacturers.

Now that the Universities generally are to be represented, such men as Playfair and Lowe will find a proper sphere, and will, we doubt not, force this matter on the attention of Government. Whether our present men in office will take up the matter is another affair; on the Continent the idea appears to be that our administrators are too busy with the political questions of the day to do anything towards the advancement either of science or art. Unhappily it needs no ghost to tell us that the "country gentlemen" who do us the honour of governing us, feel very little interest in the matter, and the so-called representatives of the trades are too much occupied with supporting strikes, to see that the prosperity of those whose interest they betray, are in reality dependent upon questions of which violent and uneducated men do not even know the existence.

But all this cannot last for ever; foreigners who only judge of us by our newspapers, ask with astonishment, "But these MM. Broadhead, Beales, and Whalley, who are they?" As soon as our workmen are properly educated they too will ask similar questions; and it will then be seen that the workman's friend is not he who shows him how to strike against his employer, but he who shows him how to develope to the utmost those great gifts of intelligence, patience, skill, and strength which for so many years made British engineers and manufacturers the astonishment of the world.

Before concluding this letter, your correspondent must again protest against the use of exhibitions as *mere* advertisements of the exhibitors. I contend that the committees to whom is delegated the power of acceptance or refusal, should resolutely refuse admittance to articles which do not show upon the face of them the condition of the industry which they represent. When Messrs. Wood and Co. send a few bottles of effervescent drinks which for all that appears might be merely water, I say they should be refused admission. They *may* be of the highest class, but as they stand in the case, they show nothing that may not equally well be seen in the window of a restaurant. It is true that one bottle, by leaking a little, tries its best to attract attention, and by pouring out a sorry libation to earth may perhaps get removed to a more congenial sphere where soda-water bottles are at rest.

To return, your correspondent trusts that you, Mr. Editor, will not think that he has dwelt too much upon the subject of the industrial education of the working-classes in this country. The question is of vital importance, and it is only by the publicity attainable through the medium of the scientific journals that the inertia of the masses can be successfully overcome.

It shall not be said that I have sent you a letter upon the Paris Exhibition in which no allusion is made to the contents of the building, so I will now proceed with my notes upon the English section.

13. Calley, Samuel, New Road, Brixham, Devon. Specimens of "Torbay," iron oxide paints, and compositions for ships, metal sheathing, etc.

The problem of producing a good sound paint of various colours suitable for wood, iron, and stucco-work, with a base of iron instead of lead, has certainly been creditably solved by Mr. Calley. In addition to extreme cheapness they are free from the deleterious character of lead paints, and are said to be much more lasting. The inventor states that a square yard of iron can be covered for one farthing, and that the labour in applying them is considerably less than with ordinary paints. In fact, from careful experiments it has been ascertained that Calley's paint brought to a working consistency with 45 per cent. of its weight of linseed-oil, covered four square yards for one penny, the labour required being only 60 per cent. of that required for lead paint. It appears from what we have been able to gather that these paints are principally made from a native oxide of iron found at Brixham in Devon. The paints produced are of two kinds. Those of the first class, which are principally adapted for iron-work, appear to be made direct from the native oxide. Variety of hue is obtained, we believe, by subjecting the ore to various temperatures.

Calley's colours of the second class are tinted by admixture with metallic substances capable of yielding the desired shades. One experiment that was made to determine the comparative resisting powers of lead paint and iron oxide paint to heat, is certainly sufficiently remarkable to deserve mention. Some sheets of iron were covered on one side with Calley's oxide paint, and on the other with red-lead. One of these, when thoroughly dry, was placed over an open coal-fire, the oxide-painted side downwards. The upper or red-lead side soon began to crack and blister, whilst the oxide-paint still adhered to the iron, and only changed its tint. In further trials it was found that at a temperature which approached a red-heat, the oxide paint was only deteriorated, while the red-lead was completely destroyed.

(From our own Correspondent.)

Paris, July 30, 1867.

Discovery of the Cromlech of El-lanic.—Ancient pottery, worked flints, and stone hatchets.

At the last meeting of the Polymatic Society of Morbihan, M. de Closmadeuc gave a description of a very fine cromlech discovered by him in a very small desert island in the gulf of Morbihan, called El-lanic, situated south of Gavara's. This cromlech is represented by more than sixty obelisks of granite, forming a vast regular circle of 180 mètres in circumference. The mean length of the blocks is three mètres. One of the blocks is of colossal size; it is broken into two fragments, and measures 5·30 mètres long by two mètres thick. A curious fact worthy of notice is that one half of the cromlech is no longer on the island but on the sea shore, so that the view of the whole circle is only attainable at low water; the sea has encroached by degrees on the island on the south side where the cromlech is found, and eaten away half the ground.

M. de Closmadeuc, who has made excavations in the neighbourhood, has discovered an incredible mass of ruins and antiquities, the nature of which cannot be doubted:—1. An enormous quantity of pottery perfectly similar to those habitually found in Celtic monuments. 2. A quantity not less considerable (several hundreds) of flints worked by man, analogous to those found in ossiferous caverns, or of Grand-Pressigny. 3. A great number of stone hatchets which have been found under the Armorican Dolmens.

The discovery of the cromlech of El-lanic is of great interest. It is most remarkable, and the most complete of the cromlechs hitherto known in the Morbihan.

Paris, Aug. 6, 1867.

Meeting of the Society of Encouragement.—Writing inks.—Decoration of porcelain.—Steam Machinery.—Industry of caoutchouc.—Reaction of oxygen on molten iron.—Researches on ozone.—Newton and Pascal.

The Council of the Society of Encouragement held its periodical meeting in Paris on the 26th ult.; M. Dumas is the chair. MM. Robert and Theurer, watch and clock makers at Chaux-de-Fonds (Switzerland), laid before the society the drawings of their great repeating clockwork and winding apparatus for clocks and watches, an appendix to the communication made by them on the 12th July.

M. Becker, Rue-de-la-Glacière, 72, Paris, offered himself as a candidate for the prize founded by M. Alexandre for the improvement of writing inks, and handed in samples of his black and violet inks.

M. Besson, ceramic lithographer made, in his name and that of M. Macé, porcelain manufacturer, a communication on the application of chromolithography to the decoration of porcelain. He showed how easy it was to transfer on porcelain and earthenware chromolithographic pictures executed on paper with the colours and varnish adapted for painting on porcelain.

M. Duprez explained a contrivance, invented by him, for a more perfect distribution of steam by a variable detent acting without the aid of an excentric. In all slide valves with a single box, according to the extent of the admission, the opening of the port is more and more narrowed, and the exhaust ports are opened sooner. M. Duprez avoids this inconvenience by the following means, the employment of which is particularly adapted for locomotives. The contrivance consists in a parallelogram fixed to the crosshead. In the model presented to the Society, the durations of the admission and the compression are sensibly the same (at equal detents), as with the much-employed system of the link valve reversed; but the new system gives the parts a greater opening by 45 per cent. An analogous combination, admitting a toothed wheel forming an epicycloidal, gives similar results, and is peculiarly adapted to stationary engines.

Mr. Balard placed before the Society the progress of the industry of caoutchouc during the last few years. Commerce has furnished, in fact, 9,000 tons of caoutchouc, the value of which is 40,000,000 francs in a raw state, and 75 to 80,000.000 francs in a manufactured state. One half of this quantity, and the purest, has come from the province of Para. The industrial demands are so important, that experiments have been made in Brazil for cultivating the tree which produces this substance, in the same way as the quinquina has been grown in the Himalaya. It is extensively used for waterproof clothing, boot soles, cards for wool, etc.; in the cards where much suppleness is required, the purest material from Para alone is used. The processes for vulcanising have also been perfected. The employment, for this purpose, of the chloride of sulphur, has become general; it has been employed either alone or dissolved in sulphide of carbon; the employment of litharge for neutralising the hydrochloric acid of moderating the sulphuration, has been better regulated. The temperature of 135°C., at which the vulcanisation takes place, has been rendered more fixed and certain by substituting, for the ordinary boiler, currents of steam. Cords of vulcanised caoutchouc are made of the pure materials, masticated with extreme care in small masses, which are kneaded together so as to form a homogeneous mass, the vulcanisation being effected by steeping the packets in water heated to a constant temperature of 135°C.

M. Troost, Professor of Chemistry, called the attention of the Society to the results obtained by properly treating cast iron at a high temperature with a current of oxygen gas. This experiment, made in 1855, by M. Henry Saint-Claire Deville, is the starting point of all the researches subsequently made. It gives the means of easily obtaining Bessemer steel, or, if it be required, a very pure soft iron. M. Troost repeated his experiment before the assembly. The cast-iron placed in a crucible of quick-lime, is fused by the combustion of a mixture of hydrogen and oxygen gases. In this state, and by increasing the emission of oxygen, the carbon, silicium, and sulphur are burnt up, and form a dross which is absorbed by the substance of the crucible; the oxygen burns the iron itself, leaving the iron in a melted state, excellently pure.

From experiments carefully made, the hydrometric commission of Lyons has established since 1852 the habitual absence of ozone in the air of that town, while its presence is constantly evident in the exterior of the city. In the month of September, 1865, the Imperial Observatory caused the same studies to be made, on an extensive scale, over all France, with a view of discovering some law, if there is one, that would explain this phenomenon. The same reagent papers were remitted to all the stations, so that they might be rigorously compared together. The observations were taken during a whole year; the results of this immense work will be, perhaps, soon known to the world. Meanwhile, M. Fournet gives the conclusion arrived at by his resumed observations at Lyons and the suburbs, with the co-operation of M. Lambert and Rassinier. While ozone was very abundant at Sauvage, on the heights of Tararæ, a range of hills separating the basins of the Loire and Rhone, traces were barely perceptible once or twice a month at Lyons. It is well known that it has been often maintained that the arrival of the cholera was coincident with the disappearance of ozone in the air. The example of Lyons does not agree well with this assertion; this city is not subject to cholera, and, at the same time, its atmosphere is always deprived of ozone.

The revelations of M. Chasles with respect to Pascal are the great topic of the day, and we wait here with impatience the news of its reception from the English press. M. Chasles is far from having furnished his last observations, as he has only placed before the public a small portion of his treasures. He is in possession of other documents which prove that Pascal had discovered before Newton, and even taught Newton, the admirable fact of the decomposition or the dispersion of light; that he was the first to make the celebrated experiment of the prism, to observe and number the seven principal colours of the solar spectrum.

The glory, also, of the employment of the word "differential," or "differential calculus," to distinguish it from the calculation of fluxions and fluents of analytical algebra properly so called, escaped Newton, to fall upon his adopted father, Pascal. Newton will not cease to be considered as a great man, but the public will cease perhaps to believe in his genius and his good faith, when it will be known that at his earliest career he was in possession, through Leibnitz, of printed and manuscript documents of Kepler; through Viviani he had the MSS. of Galileo; by Pascal, the MSS. of Descartes, even those which were brought from Sweden after his death; these latter were sunk in the Seine along with the boat which carried them, and fished up again at the old quay of the Louvre; also by Pascal, Newton had his letters, notes, thoughts on attraction, the decomposition of light, the differential method, etc. When he had such a remarkably precious store, it is not surprising that he arrived at such wonderful results, but it is astonishing that he took so long a time to put these documents in practical use. Ah! if Pascal had had the time and leisure necessary to write in French the *Principia*, with what depth and clearness would he have developed his magnificent theme!

M. Chasles possesses also a letter in which Arnaud, grieved a little at the effect produced by the first of the "Provincial Letters," wrote a most interesting word of encouragement to Pascal.

Paris, Aug. 13, 1867.

Mother of Pearl Colours applied to Porcelain.—Improvements in Calico Printing.—Engraving on Glass with Hydrofluoric Acid.—Polychromic Impressions on Porcelain.—The Spherometer.—The Exhibition Awards.—Security from Fire.—Steel Wire Drawing.—Cheap production of Oxygen.—Bleaching with Fluosilicic and Sulphurous Acids.

We have already mentioned that the Society for the Encouragement of National Industry holds, during the Exhibition, weekly instead of monthly meetings.

At the meeting on July 26, M. Maillard invited the Society to attend his experiments on the next day, at Avenue Montaigne, No. 21, Paris, to show the superiority, as regards security from fire, of his mineral roof-sheeting, compared with that of zinc or tiles. [We learn since, that the tiles and zinc gave way at once, while the new mineral covering resisted the effects of fire.]

M. Lavollée read, in the name of the Committee of Commerce, a report by M. Legentil on the manufactory of M. Teste, established at Lyons, for steel wire-drawing, in which he employs infirm workmen. This establishment has quintupled its importance in spite of the reduction of the prices resulting from the treaties of commerce, it has more extended relations with foreign countries, and in it are fabricated all important objects of steel wire-work, needles, umbrella-ribs, knitting-needles, crochets, enamelled-headed pins, pivots for different trades, springs for crinolines and corsets, etc. M. Teste announced that he employs 246 workmen and workwomen, 100 of which are employed at their homes. Besides these latter he employs about 120 young infirm females who have found a refuge in a religious institution, established near his works, and called Sainte-Elisabeth Providence of the infirm.

On the 2nd of August, 1867, M. Chevallier in the chair, a meeting was held in which M. Salvetat presented a report on mother-of-pearl colours applied to the decoration of crystal and porcelain, made by M. Briançon, decorator, Paris. He remarked that the pearl varnishes of M. Briançon were, eight years ago, objects of examination and encouragement on the part of the Society. Since then, the method has been extended to new applications, and has met with much encouragement abroad; thus we observe in the Exhibition a great number of pieces of pearly porcelain in the Belgian, Italian, Spanish, Prussian, Austrian, and Russian sections. The employment of bismuth for this purpose originated, according to Mr. Salvetat, in France.

M. Schutzenberger, professor of chemistry at the College of France, gave a very interesting lecture on his improvements in the printing of woven stuffs during the last few years. The mechanical principles adopted are the same as formerly; the means of engraving the plates have been much improved, and blocks of fusible metal are now oftener employed; also the impressions by engraved rollers have come more generally into use. Machines have been constructed for printing at one operation eight to twelve colours, and in England they go as far as twenty-four colours. The rollers are of cast iron covered with copper, and the engraving is made by the ordinary means of aquafortis; the chemical processes were the object of more extended study, since eight or twelve colours have to be fixed on the tissue by one and the same means, as they are applied simultaneously. Albumen is one of the substances most generally used. It coagulates at the boiling point of water, and retains and fixes on the tissues the colouring matter with which it is charged; it also forms a mordant for applying, on cotton, colours derived from aniline which can only be fixed by nitrogenized substances. The lecturer detailed also the processes employed in the use of garancine or madder colours, and went into a very ample description of aniline colours and their improvement, and he dwelt upon the stability and indestructibility of aniline black.

M. Peligot, member of the council, explained the processes generally in use, for engraving on glass by hydrofluoric acid. This acid in a liquid state gives a polished and transparent surface to the glass, and is useful for making decorative designs on white glass lined with coloured glass. Dull engravings on glass are obtained by the use of neutral fluorides, to which acid has been added. M. Kessler applies these processes at Baccarat; they are also used at Saint Louis. This last establishment consumes annually 800 kilog. of hydrofluoric acid; Baccarat employs more. The designs are first drawn on stone, and proofs are taken off with an ink containg wax and bitumen, on unsized paper, coated with starch first, then with gum, and thirdly with collodion. When the sheet is applied to the glass, the paper is washed off with water, leaving only the impression and the coating of collodion which covers it. A similar proceeding is employed for polychromic impressions upon porcelain, the collodion being burned off in the fire. Five hundred large sheets of glass engraved in this manner, measuring 2m. 20c. long by 60c. wide, have been made for the establishment of M. Duval, in Paris.

M. Perreux, engineer, explained the principles of his *spherometer*. It consists of a screw, the pitch of which is a quarter of a milimètre, and a circle divided into 500 parts, so as to obtain the graduation of 1-2000th of a millimètre. He also explained the construction of a self-acting machine, capable of marking, in a right line, divisions visible by the microscope, only the thousandth part of a millimètre asunder.

Among the many persons of great merit in the French section of the Exhibition who have been either badly rewarded, or passed over in silence, we cite the following: M. Collas, the pioneer of benzol, inventor of nitro-benzol, and classed by the Society of Mulhouse among the discoverers of aniline colours; he has exhibited at the Paris Exhibition two important discoveries, and the jury have not awarded him even honourable mention. What has become of the medal certainly awarded him by the jury at the first meeting?

M. Dubrunfaut, discoverer of the application of osmose to the extraction of sugars, exhibited by M. Camichel de la tour du Piu (Isere), a successful operation, greatly extolled in three lectures by M. Payen, a most excellent judge, at the *Conservatoire des Arts et Métiers*, at the Sorbonne, and at the Society of Encouragement, has been completely ignored.

The "Mille" gaz, and gazo-lamp, the former of which is remarkable for the facility with which gas is produced without any mechanical agent or fire, by an apparatus easily put up anywhere; and the latter now sold by thousands all over Paris, and in the Provinces, besides being exhibited in hundreds of different shapes and designs at the Exhibition, do not figure even in the catalogue.

A noble widow, Madame de Clercq, spent £140,000 in order to render the commune of Oignies, in the Pas de Calais, in which she resides, a terrestrial paradise. She has constructed at her expense a vast church, an asylum, a school and work-room for girls, a boy's school, a house of patronage for youth, an asylum for the aged, cheap dwellings, etc.; she has founded courses of studies for adults, Sunday-schools, a library, a club, recreation and exercise-rooms, with medical consultion, a savings' bank, etc. A group of neighbouring roads has also been organized and kept in repair, more than 400 acres have been cleared and let out to 550 families, a coal mine has been sunk, and water supply given to the town, now numbering 1800 souls, all at the expense of this lady, to whom the jury have awarded the humble prize of a silver medal!

The aim of the Agricultural Society of Entomology is to contribute to the multiplication of useful insects, and to promulgate the means of destruction of noxious ones. It is composed of honorary and titular members, without any limit as to their number. The title of honorary member can be conferred on persons who, by their publications and works, forward the views of the Society. It can be also conferred upon persons who aid the Society by their patronage or donations.

Any person, without distinction of residence or nationality, can be received as titular member and correspondent of the Society, by being presented by a member of the Council, adhering to the statutes, and paying ten francs per annum. From time to time reports are issued relative to the multiplication of insects useful to man, and the destruction of those hurtful, indicating the rational means of healthy development; in the other case the most ready method of extirpation. There are being formed a library, collections, and a museum; also, the documents and papers received are centralized and classified, and those intended for publication are indicated. An enquiry office has been instituted, in which interested parties can obtain information on the insects about which they desire it.

Every two years an exhibition is organised in Paris, of useful insects, their products, and apparatus adapted to their cultivation; and of noxious insects, the ravages caused by them and their means of destruction.

The process for the cheap production of oxygen, by M. Tessie de Motay, has perfectly succeeded in the laboratory of the Exhibition established on the banks of the Seine. The new method, so simple and efficacious, has fulfilled all expectations. Fifty kilog. of manganate of soda give 400 to 450 litres of oxygen per hour, after eighty successive reoxidations. M. Tessie de Motay has so perfected the fabrication of manganate of soda, that he is almost certain of being able to furnish it to the trade at the price of 30 or 40 centimes the kilogramme. The necessary arrangements for essaying on a large scale the oxyhydrogen light at the Hotel de Ville, in the square as well as in the interior, advances rapidly, and the generators are fitted up already in the cellars. Oxygen and common gas burned together in common burners increase the illuminating power from 1 to 8 or even 15, or can serve at the same time for burning in the chloride of magnesium lamps of M. Carlevaris, which do excellent service.

In order that the essays of spontaneous bleaching with fluosilicic acid and sulphurous acid could completely succeed, it was necessary to render as cheap as possible the production of manganate of soda. Applied to pulp of wood and straw it gave such excellent results that the manufacturers themselves scarcely knew whether they were treating rag-pulp or straw-pulp.

F. Moigno.

REPORTS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

On the Absorption of Gases by Metals, By Dr. Odling, F.R.S., *etc.*

(*Continued from p.* 144.)

You observe in the case of all the metals we have as yet considered, that they are characterised by absorbing chiefly one particular gas. Platinum and palladium are characterised by absorbing hydrogen alone; and copper also, by absorbing hydrogen. Whether it absorbs any other gases has not, I believe, been determined. In the case of gold, the gas absorbed most abundantly is hydrogen, though it is certainly capable of absorbing a great many others. Now, with regard to silver, we find that it has the special property of absorbing oxygen gas. I am not referring to the temporary absorption of oxygen by melted silver, and its evolution on the solidification of the metal, which constitutes the well-known spitting of silver, but to the occlusion of the gas by the solid metal—for it is not merely an absorption, it is an occlusion, the metal retaining the gas for any length of time; and you will remember that, when speaking of platinum, I mentioned that the metal retained its hydrogen for two months, although exposed freely to the air. In different experiments, then, silver wire was found to absorb 74 per cent. of oxygen, and nearly 21 per cent. of hydrogen. Silver sponge absorbed 722 per cent. of oxygen; 92 per cent. of hydrogen; 52 per cent. of carbonic acid, and 15 per cent. of carbonic oxide. A specimen of silver leaf exposed to the air at a red heat absorbed 137 per cent. of oxygen and 20 per cent. of nitrogen. Accordingly, while ordinary atmospheric air contains 21 per cent. of oxygen, and the air absorbed by gold only 5 per cent. of oxygen, in the air absorbed by silver the oxygen amounts to 85 per cent.

Now we come to another metal, and of very great interest in relation to this occlusion of gases—namely, iron. Ordinary iron wire was carefully cleaned, heated in vacuo to drive off its natural gas, and then charged with different gases at a red heat. It was found that the wire, treated in this way, absorbed 46 per cent. of hydrogen; but there was another gas which it could absorb in a much larger proportion—namely, carbonic oxide. Just as platinum is distinguished by its copious absorption of hydrogen, and silver by its absorption of oxygen, so is iron distinguished by its ready absorption of carbonic oxide. Whereas it absorbed only 46 per cent. of hydrogen, it actually absorbed 415 per cent. of carbonic oxide.

A point of interest connected with iron, as with platinum, is that the metal, though perfectly impervious to gas at ordinary temperature, yet when strongly heated, allows the passage through it of hydrogen gas, as shown by M. Deville, and of carbonic oxide, as shown more especially by Mr. Graham, whose admirable elucidation of the nature of these transmissions, forms the subject of our consideration this evening; and who has shown that in the case of iron, as in that of platinum, the transmission of the gas is preceded by its absorption in the substance of the metal.

With regard to the natural gas of iron wire—that is to say, the gas existing in the metal as ordinarily met with,—I may direct your attention to the particulars of one or two experiments. In one experiment, the wire heated in vacuo was found to give off 7·94, which we will call 8 times its volume of gas, while in another experiment, in which the heating process was kept up for a much longer time, it gave off 12 times its volume, or 1200 per cent. of natural gas, consisting chiefly of carbonic oxide. Whence it would appear that ordinary wrought iron occludes in the forge, and continuously retains, from 8 to 12 times its own volume of natural gas.

Now iron has two distinct origins. In addition to what we may call terrestrial or telluric iron, there is another kind of iron which we may call sidereal, that is to say the iron of meteorites. Hence it becomes a question of interest to ascertain whether this meteoric iron contained any gas, and if so, what was the nature of the gas; because it would appear, from the existence in the different metals examined of what may be called natural gas, that every metal contains a residue of the gas in which it last existed at a temperature of ignition. If the metal has been last ignited in hydrogen it retains hydrogen, if the metal has been last ignited in carbonic oxide it retains carbonic oxide. Does meteoric iron then contain any gas? and if so, of what kind? For the purpose of ascertaining these points, a quantity of meteoric iron from the Lenarto fall, of about 45 grammes by weight, and six cubic centimètres by volume, was taken, cleaned, and introduced into a porcelain tube of this kind. A vacuum was made in the tube, and heat then applied, when so soon as the meteorite got red-hot, it began to give off some gas; and here in this repetition of the experiment, I hope to show you some of the gas which this meteorite has brought down from—who can say where. There we have the porcelain tube, containing the meteorite, exhausted by the air-pump and being heated by the furnace. One end of the tube is closed; the other end connected as you see with the Sprengel pump. The mercury is now falling in the Sprengel pump, and as it falls is delivering the gas. In this test-tube we are now collecting the gas extracted from the meteorite, and which the meteorite has brought down from the place where it last was at the temperature of ignition.

Now comes the question, what is the nature of this gas? Well, the 45 grammes or 6 cubic centimètres of iron were ignited in this way for two hours and a half, and during those two hours and a half, they gave off 60½ cubic centimètres of gas, which I may say at once consisted substantially, not of carbonic oxide—the gas existing in terrestrial iron which has been last ignited in a coal furnace—but it consisted substantially of hydrogen, or contained, at any rate, 85½ per cent of that gas, with a small quantity of carbonic oxide and nitrogen. Whereas, then, telluric iron contains carbonic oxide absorbed from the atmosphere in which it has been last ignited, this siderial iron contains hydrogen instead, absorbed, I suppose, from the atmosphere from which it has been last ignited. My distinguished friend, Mr. Miller, in co-operation with Mr. Huggins, has demonstrated the existence of hydrogen gas in celestial bodies by an analysis of the spectra of several of the stars; but we have got, in this test-tube, the thing itself. Here is the free hydrogen gas which has been brought down to us by one of these smaller stars. Perhaps a point of still further interest, relating to this subject, is the classification of the stars according to their spectra, which Father Secchi has recently made. He has divided the fixed stars into three classes, in one of which, typified by *a* Lyræ, the spectrum is essentially the spectrum of hydrogen. That star, then, undoubtedly contains an atmosphere, of which the prevailing constituent is hydrogen gas. Now, upon a subject of this kind, which is only three days old, it is not in human nature to avoid speculating a little; and I think we may venture to speculate thus far, that our meteoric iron probably absorbed its hydrogen from a star-atmosphere of the class which is so typified.

But there is another point bearing upon this subject. Under ordinary circumstances, we are not capable of getting into iron more than half its volume of hydrogen; but this natural iron contains nearly three times its volume of hydrogen. Now, if under ordinary atmospheric pressure, iron will absorb only half its volume of hydrogen, what sort of a pressure would it require to enable it to absorb six times that quantity? According to our present notions, it must at any rate have been exposed to an atmosphere in a very condensed state. We can not imagine that, in the interplanetary space of our ordinary solar system, there should be gas of a sufficient density to permit the absorption by this meteorite of six times the quantity of hydrogen absorbable by iron under the pressure of our telluric atmosphere.

We have now succeeded in extracting a considerable volume, many cubic centimètres, of gas from our ignited meteorite. I almost think, although the experiment is but a small one, that, as we have hydrogen brought from so great a distance for our examination, it is worth while to darken the theatre in order to witness its combustion; and having lowered the theatre-gas, we will now inflame our hydrogen of the stars. [The meteoric hydrogen was accordingly ignited.]

So much, then, for the great fact of the absorption and occlusion of different gases by metals. Now we have to consider what is the nature of the absorption. In the year 1823, Mr. Faraday established the general proposition that a gas was nothing else than the vapour of a volatile liquid, existing at a temperature considerably above the boiling point of the liquid. In the case, for instance, of liquid water, which boils at 100°, if the vapour of this water be afterwards heated up to a temperature of 150°, the water-vapour existing at the temperature of 150° is a true gas, possessing all the physical properties of a gas. If we take this water-gas existing at 150°, and cool it down to a little above the temperature of 100°, it loses some of the characteristic properties of a gas, and becomes what we more strictly call a vapour; and this vapour, if subjected to a temperature ever so little below 100°, at once becomes converted into liquid water. Accordingly, the boiling part of liquid water may be equally well called the condensing point of water-gas: and similarly, in case of other gases, their respective condensing points are merely the boiling points of the liquids producing them. But the boiling point of a liquid, and the condensing point of its gas, is not a fixed point of temperature, but is a point of temperature varying with the pressure to which the gas or liquid is subjected. For instance, under ordinary atmospheric pressure, water boils at 100°, but under the pressure of five atmospheres it boils at 150°, so, that if we take our water-gas existing at 150°, and maintaining its temperature at 150°, then subject it to a pressure of five atmospheres, its temperature will no longer be above the temperature of its boiling point, and it will cease to exist as a gas at all, and become converted into liquid water. Accordingly, we may effect the condensation of water-gas, existing at any temperature, by cooling it down to its ordinary condensing-point, or by subjecting it to a degree of pressure at which its existing temperature will not exceed that of its thereby heightened condensing-point. And so with other gases. Every one of the very many different gases known to the chemists, with about six exceptions, has been condensed into the liquid state, by a certain reduction of temperature; or by a certain increase of pressure; or by a conjoint reduction of temperature and increase of pressure, until the temperature of the gas has been brought below the heightened condensing point or boiling point corresponding to the increased pressure.

Now let us consider more minutely, for a minute or two, the effect of pressure upon these condensable gases, taking water-gas as an illustration. Suppose we take water-gas existing at 150°, and contained in a cylinder closed in by a movable piston, which is balanced, or weightless. Supposing the area of the piston to be one square inch, the water-gas is subjected to a single atmospheric pressure, which is equivalent in this case to 15lb. Now if we place a 15lb weight upon the piston, we shall double the pressure, and consequently halve the volume of our water-gas. In order to reduce this gas to one-fifth of its original volume, we shall have to quintuple the original pressure, by placing four such weights upon the piston. But at a pressure of five atmospheres the temperature of the gas, or 150°, would cease to be above the temperature of its condensing point; and the gas, instead of being merely compressed into one-fifth of its original volume, would cease to exist as gas at all, but become converted into a scarcely appreciable volume of liquid, and the piston would descend to the very bottom of the cylinder. Accordingly water-gas at 150°, being condensable by a pressure of five atmospheres, it is impossible to reduce it to one-fifth of its bulk without liquefying it. And, similarly, with other gases. Ordinary ammonia gas being, at ordinary temperatures, condensable by a pressure of seven atmospheres, it is impossible to reduce it to one-seventh of its volume without liquefying it. Take, again, the case of sulphuretted hydrogen gas. That being condensable at ordinary temperatures, under a pressure of 15 atmospheres, it is impossible to reduce it to one-fifteenth of its bulk without liquefying it. Hydrochloric acid gas being condensable at ordinary temperature by a pressure of 40 times the ordinary atmospheric pressure, it is impossible to compress this gas into one-fortieth of its bulk without reducing it to the liquid state. And, in general, a gas maintained at some definite temperature, cannot be reduced to a bulk less than that corresponding to the pressure necessary to liquefy it, without its becoming liquefied. Conversely, the reduction of any gas to a bulk less than that corresponding to the pressure necessary to liquefy it, must be taken as evidence of its liquefaction.

Now, although oxygen and hydrogen gases have never yet been reduced to their liquid state by mere pressure, there is strong reason to believe that these and other gases, absorbed by heated metals, really exist as liquids, or, at any rate, do not exist as gases within the substance of the absorbing metals. For these two gases have never been reduced to less than $\frac{1}{800}$th of their bulk by mere pressure, but when absorbed by massive iron, platinum etc., they are seemingly reduced in bulk many thousand-fold. Moreover, all gases, even the most insoluble, are certainly liquefiable by solution. Here I have an experiment arranged to show the liquefaction of gases by solution and absorption, with a view to suggest the analogy subsisting between the absorption of gases by liquids and by heated metals. This sealed tube is filled with ammonia gas, and on breaking the end of the tube under coloured water, you observe that the gas is absorbed in an instant, the water rushing up to the very top of the tube. Now ammonia is one of the most soluble of all known gases, but, notwithstanding its great and rapid absorption, which you have just witnessed, it is in reality less soluble in, or absorbable by water, than hydrogen is absorbable by palladium. At mean temperature one volume of water absorbs about 780 volumes of ammonia, whereas one volume of palladium absorbs 643 volumes of hydrogen measured at 17·5, which would exceed 800 volumes measured at 97°, the temperature of the experiment.

Now, this absorption of soluble gases is manifested, not only in the case of liquids, but also in the case of soft solids; those which Mr. Graham has denominated "colloids." Accordingly, if we take a little hard white of egg, a substance which is not wet in the ordinary sense of the word, and if we pass it up into ammonia gas, you see that the white of egg absorbs the ammonia gas with almost as much rapidity as did water itself. Now one possible view, in connection with the absorption of gases by heated metals, is that these metals are in what may be termed a colloid state—that is to say, that they are soft bodies, or imperfect solids, and that a species of low form of chemical action takes place between the metal and the gas, allied somewhat to the low form of chemical action which leads to solution, or to the absorption of gas by soft solids, such as white of egg and india-rubber.

There is one further point to which, in the few minutes that remain to me, I wish to draw your attention, and that is the absorption of gases by such substances as charcoal, for it is a question whether the absorbtion of gases by heated metals may not be allied in some degree to this well-known phenomenon; and certainly there are some facts, at any rate, which seem to indicate a very close relationship between the two acts of absorption. If we take a piece of compact charcoal, and pass it under metallic mercury into a cylinder of ammonia gas, we see in this case a somewhat rapid absorption of the gas; and I have no doubt that, in the course of a few minutes, the piece of charcoal will absorb the whole of the gas originally existing in the cylinder. Now, we know that this absorption of gas by charcoal varies considerably with the temperature of an experiment, the nature of the gas, and above all with the texture of the charcoal employed, just as does the absorption of gas by metal. Thus, in the case of platinum, the fused metal absorbs but a very small quantity of hydrogen, the spongy metal absorbs a larger, but still a comparatively small proportion; whilst the feebly porous metal, in the form of wrought platinum, alone manifests the property of absorption in the highest degree. Again, it is well known that the gases absorbed into charcoal have their chemical properties intensified, just as I have shown you with regard to the hydrogen absorbed by palladium. Further, the property of charcoal to absorb different gases is intimately related to its property of exerting a selective absorption of liquid and dissolved substances. Now we find this property also manifested by palladium. Thus 1,000 volumes of palladium foil were found to absorb 1 volume of water, 5½ volumes of alcohol, and 1½ volumes of ether, results showing a special relation of palladium to those different liquids, corresponding to the action manifested by charcoal. Moreover, this selective absorption of different liquids by a sort of capillary affinity, brings the absorption of gases by palladium into relation with some very familiar phenomena, at first sight of a widely different character, namely, the selective absorbtion of dyes by different tissues, and the action of mordants; the property which charcoal has of abstracting various matters from solution, being closely allied to that by which certain tissues and mordants abstract colouring matter.

There are many other points of very considerable interest, in relation to this subject, which I should be glad to bring before you, were not my time already expired; but there is one point of practical importance, connected with the absorption of gases by iron, which I ought not to omit, namely, the bearing which these facts have upon the conversion of iron into steel. Steel is manufactured, as we all know, by the application of charcoal to bar-iron at a certain temperature. The charcoal, it is true, gets partly converted into carbonic acid and carbonic oxide, but it is only the surface of the iron which is in contact with either the charcoal or its oxides; nevertheless the conversion of the metal into steel takes place through its entire mass. Now, it has hitherto been a subject of great difficulty to explain this penetration of the carbon, or carbon-oxides, into the centre of the iron bars. But we now see that iron, like a colloid or porous substance, has the power of absorbing carbonic oxide gas to its very centre. And it would seem that the process of acieration—the conversion of iron into steel—really consists in an absorption of carbonic oxide by the metal, and a subsequent decomposition of the absorbed carbonic oxide, into carbon, which effects the conversion of iron into steel, and into carbonic acid gas, which escapes from the surface of the metal, and gives rise to the blisters by which freshly made steel is characterised. The eliminated carbonic acid then takes up more carbon, to become reconverted into carbonic oxide, which the metal again absorbs, and so on continuously until the process is completed.

In conclusion, it only remains for me to express what I am sure we must all feel—our sense of indebtedness to Mr. Graham for his admirable investigations, which have not only added largely to our knowledge of the transmission of hydrogen through ignited platinum and iron, observed by M. Deville, but have gone very far to explain the nature of the phenomena, by showing that they differ altogether in character from the phenomena of diffusion, but are preceded by an occlusion and probable liquefaction of the gas in the substance of the metal, somewhat similar to the occlusion of soluble gases by water, or of absorbable gases by charcoal, in virtue, probably, of a low form of chemical affinity subsisting between the gas and the metal. They have brought to light the startling fact of the occlusion of some of the lightest gases by some of the heaviest metals, to the extent of several times their volume, and, in the case of palladium, to the extent of several hundred times its volume. They promise, moreover, to throw great light upon a very important branch of manufacturing art—namely, the conversion of iron into steel. They have also given us a new illustration of the strange relationship so frequently existing between apparently the most remote phenomena, as the acieration of a piece of iron and the dyeing of a piece of silk. And, lastly, in the case of the meteoric iron, they have afforded us a further demonstration of the oneness of the universe, of the extension of one chemical system throughout the entire cosmos.

A Course of Four Lectures on Spectrum Analysis, with its Applications to Astronomy. By William Allen Miller, M.D., F.R.S., *etc.*

Lecture IV.

(Concluded from page 142.)

Spectra of the Fixed Stars.—Mode of Observation.—Double Stars.—Variable Stars.—Temporary Bright Star in Corona.—Nebulæ.—Clusters.—General Conclusions.

A great number of other stars have been examined. I cannot, however, attempt to give you any idea of their composition in detail, but must refer you to a list which you will see here, giving the names of the more important stars, which we have examined more or less completely. Among the most interesting of the stars we have examined are Sirius, Arcturus, Capella, Vega, Pollux, Castor, Cygni, Procyon, and α β and γ Andromedæ, Rigel, Spica Virginis, α Aquilæ, Cor Caroli, Regulus, and others. The general result of these investigations shows that the stars are bodies, formed upon the same plan as our sun, each differing in composition from its fellows, but all apparently containing matter, some portion of which is identical with that composing a part of our own globe.

One or two of these stars may be advantageously referred to more fully. Among these a red star β Pegasi is much like the star α Orionis in its general character, but it is much fainter. It is one of the third magnitude. Here, we have been able to measure only twenty lines. We can see that it is full of lines, but the uncertainty of the atmosphere and the difficulty of seeing these lines with precision have prevented us from accurately fixing the places of a larger number. It contains sodium and magnesium—two of the same bodies which are present in Aldebaran; and besides that, it is probable, though we have not been able to verify all the principal lines, that barium, iron, and manganese are present.

Let me now call your attention to the colours which the stars exhibit. It is a matter of familiar observation that the stars differ in their tints. This difference appears to be caused, in many cases, by the atmosphere outside the photosphere, which causes an absorption of certain colours contained in their light, and in consequence of this we have a difference in the tint. It is remarkable that in some of the red or orange stars, like β Pegasi, and others, hydrogen is absent, whilst in the white stars this element is predominant. In the spectrum of the important star called Vega (α Lyræ), sodium, hydrogen, and iron have been found. It might be supposed that the star Sirius, the brightest of all the stars, would have given us more information than all the others; but it is not so. I will throw its spectrum upon the screen, and you will see that it is remarkable for the absence of strong lines. The light of Sirius is white. There are only three important lines in its spectrum, and these correspond exactly in position with the lines of hydrogen. With these exceptions, the lines of Sirius are feeble. I do not mean to say that there are not other bodies in the stars besides hydrogen, but the proportion of those other bodies must be so small, and the vapour so dilute, that the whiteness of the light is not subdued by them in any remarkable degree. Here are lines which correspond to F and C; here is a line in the blue; and here is one which we constantly find in all the stars, the double sodium line D. Here is the magnesium line; and here is one which is probably due to iron.

Let me now call your attention to the varieties in colour which the stars exhibit. Sirius, as I have said, is a white star. There are stars which have an orange, or yellow, or ruddy tint; and, again, there are others which are blue, or green, or purple.

The examination of these coloured stars is often a matter of great difficulty, because in general their luminosity is small, and frequently these coloured stars occur in pairs, constituting what are known as double stars. It often happens that a bright orange-coloured star has a faint blue or green star as its companion; and this companion is often so close that it is a matter of considerable difficulty to separate the spectra of the two stars, though we can see them in the telescope distinctly enough. In order to separate the spectra of two stars, it is needful so to arrange the motions of the telescope that the spectra shall be always at right angles to the line joining the two stars, so as to maintain the two spectra parallel to prevent them from overlapping, and so interfering with one another. I will take first an orange-coloured star, the brighter of the double stars which constitute Hercules; in the spectrum of this star on the screen, you will see the orange and yellow predominating, whilst other portions of the light are subdued in consequence of the presence of a large quantity of absorbent matter, which stops certain rays in the blue and violet portions of the spectrum. You must bear in mind that in throwing these images upon the screen we are under a considerable disadvantage, because though they are tinted to give you an idea of the relative position which these lines occupy in the spectrum, they do not by any means represent with accuracy the colours which the star itself would show. You will see in the red part of the spectrum there are three or four strong lines, but in the orange and yellow there are comparatively few, so that the star shines with an orange light in consequence of the absorption of the green and blue portions.

I will now take one of the double stars, β Cygni, and project an image of the orange star, with its blue companion, on the screen. The orange star is the most brilliant one. The blue star is so faint upon the screen that you can hardly see it from a distance. You may imagine from this what is the difficulty in seeing, and still more in measuring the position of such faint lines as these. Let us now examine the spectra of the two stars. That of the orange star is characterised by a large number of bands or lines in the blue and green portions, and comparatively few in the yellow portions. In the spectrum of the blue star we have scarcely any lines in the blue, but a large number of lines in the yellow and orange, and in some parts of the red.

We have here, then, examined two classes of stars—some which have a considerable brilliancy, and others in which we have them varying in colour; but there are other variations in the stars, respecting which the spectroscope, we may hope, will at some time or other afford information. Some of the most remarkable amongst the stars are variable in their lustre. At times they shine out with a high brilliancy, and at others they become reduced and almost disappear from view. One of the most interesting problems demanding solution in the nature of stellar bodies, is the explanation of this singular periodical variation. Sometimes these periods are tolerably regular, occurring after a few days, or a few months, or sometimes after years. At other times the periodical variations in the star are irregular; that is to say, though the light of the star waxes and wanes in intensity it does so at irregular intervals. One single observation seems to show, so far as it goes, that there is hope of further progress in this direction. The star α Orionis, one of the first whose spectra I projected on the screen, is a variable star. It is one, however, of which the variation is not very wide. It varies, perhaps, half a degree in magnitude. We found, on making observations when it was at its maximum, that a certain group of lines which were observed two years before, when it was at a low state of illumination, had disappeared. Their position had been carefully measured during a period of minimum, but these lines were not found when the star was at its maximum.

There are, however, others falling under this class of variable stars which are still more remarkable. They have been called temporary stars. One of the most prominent of these was noticed on November 7, 1572, when Tycho Brahé, in returning one evening from his observatory, saw persons gazing at a star which he knew was not visible half an hour before. It continued to increase in brightness for some weeks, but in the course of a year it gradually dwindled away. This star has been altogether lost sight of, and no one knows its true position. In October, 1604, a star, equally bright, appeared in Serpentarius. It almost rivalled Jupiter in brightness. It afterwards faded away and disappeared. In the year 1848 Mr. Hind observed a smaller star, in Ophiuchus, of a ruddy colour, which came out and disappeared in the same sort of way. Lately we had an opportunity of watching one of these stars, which has thus blazed out, and rapidly died away. It was even more brief in its blazing forth, and more rapid in its disappearance, than any of the others; but, happily, at the moment the opportunity offered, we were prepared to examine its light by means of the spectroscope. Mr. Birmingham, of Tuam, first saw it in Ireland, on the 12th May, 1866. He informed my friend Mr. Huggins, who received the news of its presence on the 16th May, and by the same post, Mr. Baxendell, of Liverpool, directed his attention to the star. No time was lost. On the very same evening on which the intelligence arrived, as it happened to be a fine night, we directed the telescope to the spot, and we were able to discover a most remarkable state of things. I shall project on the screen the image of this star. It blazed forth in Corona. About the time Mr. Birmingham saw it, it was of the second magnitude. It occupied the position of a star of the ninth or tenth magnitude noted by Argelander. You will observe that the spectrum of this star is crossed as usual by a number of black lines in the luminous coloured portions; but, besides that, you will see some very bright bands of light—four strong lines, and a fifth much fainter in the blue. We had never seen such lines in any solar or stellar observation before, and they are evidently connected with a new, and, as it turned out, a transient state of things. Two of these lines occupied the position of the lines of hydrogen. One corresponding to the line C in the solar spectrum, and another to the line F. There are two strong brilliant lines in the blue, the nature of which we were not able to ascertain. The duration of the outburst till it dwindled down to a star of the seventh or eighth magnitude, was but a week, so that the opportunities of making observations and measurements were but few. In this star, then, we have three different spectra. First, we have a photosphere giving out a continuous spectrum, and over that we have the usual state of the solar and stellar atmospheres; that is to say, an atmosphere filled with luminous vapours, capable of absorbing a part of the light behind: and then, outside that, more brilliant still, is a luminous spectrum of glowing gas, as though the star was suddenly involved in the flames of hydrogen combining with some substance the nature of which we do not know, but which may be—probably is—connected with the two unexplained brilliant lines in the blue. I say this star, at the time of this outburst of light, was in a condition in which a sudden and violent action upon the hydrogen occurred, in consequence of which, probably the whole mass of the star was raised in temperature, and its luminosity consequently was increased, but the temperature of the mass of the star was not brought up to the same point as the temperature of the hydrogen by which that incandescence appears to have been produced. What the origin of this hydrogen was, of course it would be vain and idle to speculate. But the presence of hydrogen is certainly revealed by the observations just described. Moreover, the hydrogen must have been in a state of active incandescence which may be supposed to be the cause of the luminosity of the star, and just as a glowing ball of lime is heated up in the nearly lightless flame of the oxyhydrogen jet, so the nucleus of this star was lighted up by an outburst of hydrogen suddenly brought to an intensely incandescent condition. It is clear that this observation could not have been made without the aid of the spectroscope, for on viewing a star through the telescope all that can be seen is limited to variations of colour and brilliancy; we can never magnify a star so as to produce anything more than a point of light. We can never get a disc. We have simply an increase in the intensity of the light as we increase our telescopic power. Among the most remarkable of the variable stars is η Argus, the spectrum of which seems to demand careful study.

I must now pass on to a totally different series of objects —the *nebulæ*. Scattered over different parts of the heavens are a number of remarkable bodies which look like patches of light or luminous clouds. In some cases they are collected into rings; in others into spirals, whilst in other instances they assume still more definite forms. These nebulous masses of light have ever since their discovery excited in a high degree the wonder and curiosity of those who have examined them. The interest they awaken is perhaps still further increased by a remarkable speculation concerning them put forth by Sir William Herschel, when he asked whether it was not possible that these nebulæ might be the primordial forms of matter from which stars and suns and their attendant planets had been produced. Notwithstanding minute and careful observations by the telescope, nothing was known of the physical condition of the matter comprising these nebulæ. It was not even known whether they were aggregations of stars so infinitely distant from us that we could not discern the separate stars, or whether each nebula was a separate luminous object of a nature entirely different from the stars. Mr. Huggins has been enabled in several instances to show that the nebulæ are not stars, but that they are composed of glowing gas; and, farther than that, he has been enabled to give some hint as to what this gas may be. I must now ask you to look at the photographs of some or these bodies, which I shall throw upon the screen; many of them have been taken from the beautiful drawings of Lord Rosse. When Mr. Huggins was examining one of these nebulæ with his spectroscope for the first time, he observed what appeared to be a single vertical line of light, this on closer inspection was seen to be accompanied by two fainter lines in the more refrangible portion. This observation immediately gave him the key to the nature of these bodies. The first nebulæ that he examined was a comparatively brilliant one in Draco (37 H iv.). The nebulæ are usually referred to by letters and numbers, which represent the position of these bodies in certain catalogues drawn up by astronomers of eminence. This nebula in Draco, then, instead of giving a continuous spectrum, crossed by black lines like the stars, was found to give three lines of light only, and the greater part of the light was concentrated into one of these three lines. Indeed, had it not been for this circumstance, the light of the nebula is so excessively faint that it would have been impossible to see it at all as spread out in a continuous spectrum, and, in fact, my friend scarcely expected that it would be possible to get any accurate observation in consequence of the faintness of the light. The result, however, amply rewarded him for his trial. You observe upon the screen a spectrum consisting of three lines only. They are here exaggerated very greatly in brilliancy, for the purpose of rendering them visible at all. Below the representation of the spectrum of the nebula on the diagram are the bright lines which correspond most nearly with its lines. This line F corresponds exactly with the faintest of the three lines in the nebula. It is very difficult in diagrams of this kind to preserve the true relation in brilliancy of these lines to each other. At the less refrangible end there is no line corresponding to the red line of hydrogen. An important observation made by Plücker upon rarefied gases in tubes may have a bearing on this point. He found that as hydrogen becomes rarefied, its red line disappears. Hence the absence of the red hydrogen line in the nebula may be connected with the attenuated condition of its gaseous materials. In the diagram you will see three other lines occurring in the solar spectrum. Those are lines which correspond to the group of magnesium lines. The brightest and most refrangible line in the spectrum of the nebula corresponds to one of the brightest lines of nitrogen. It is remarkable, however, that the other lines of nitrogen are absent. This second line in the nebular spectrum does not correspond to any of the lines that are known to us, but the nearest known to it is one of the lines of barium. It must not be supposed that all the nebulæ are exactly like this one. Of the sixty which Mr. Huggins has examined, about twenty exhibit the bright lines due to matter in its gaseous state, all of which contain the bright line corresponding to that of nitrogen; in some the other fainter lines are not seen. Such spectra, therefore, are not produced by a group of stars; not by a substance like any others that we have seen hitherto in the heavens; they must be furnished by masses of glowing gas, which are giving out light of these three particular degrees of refrangibility.

Besides these true gaseous nebulæ there are a vast number of others, but in some of them the luminous material is connected in such a way that they appear in the telescope like clusters of minute stars, or they look as if condensed into little points of greater luminosity than others. Now, when such clusters are examined by the spectroscope they are found to furnish continuous spectra crossed in some cases by the same light lines produced by the nebulæ which are wholly gaseous, so that here the nebulæ appear to consist of two portions, one still gaseous, the other undergoing a sort of condensation. One dares hardly to speculate upon these matters in the present state of our knowledge. It is so easy to speculate and get wrong, and thus to fix notions in one's mind that it is not easy to get rid of again. The truly philosophical course here is simply to form such a hypothesis upon the facts observed as shall serve to guide us in our further investigations.

My friend, Mr. Huggins, has placed a large number of his beautiful drawings of nebulous bodies at my disposal. I can only select one or two for exhibition on the screen. There is a nebulæ which has a remarkable shape like that of the planet Saturn. All these nebulæ have a particular faint bluish green light. Here there are the same three lines. Here, again, is a remarkable spiral nebula (80 H iv.), which has been very carefully observed by Lord Rosse. You will see the style and character of its construction. But it is also remarkable for its brightness in comparison with some of the others. Besides the three lines previously noted we observe a further bright line which is more refrangible than the others. The gaseous character of this nebula is distinctly seen. I will now take a nebula which is not gaseous, and which is visible to the naked eye—the well-known nebula in Andromeda. There is a concentration of light in its nucleus around which is expanded into a longitudinal form. It does not give a spectrum with bright lines, but a continuous spectrum with certain peculiarities. The orange and red portions are almost absent, and the other portion has a mottled appearance, which it is scarcely possible adequately to represent upon the screen. Here is a table which will give you an idea of the character of the nebulæ examined by Mr. Huggins, and the results of his observations compared with the purely telescopic observations of Lord Rosse, as furnished to Mr. Huggins by Lord Oxmantown:—

	Continuous spectrum.	Gaseous spectrum.
Clusters	10	0
Resolved or Resolved?	5	0
Resolvable or Resolvable?	10	6
Blue or green, no resolvability,	0	4
or resolvability seen	6	5
	—	—
	31	15
Not observed by Lord Rosse	10	4
	— 41	— 19

Here are the results which were arrived at by Lord Rosse by observation with his colossal reflecting telescope. First of all are ten clusters, and amongst these clusters all give a continuous spectrum. None of them appear in the spectroscope to have a gaseous spectrum, so that the observations of the telescope and spectroscope correspond. The second line represents to us a certain class of bodies which, though they have not actually been resolved into separate stars as the others have been, yet appear to be resolved. None of the bodies exhibit gaseous spectra. On the other hand, amongst those which have a blue or green colour there are none which are not gaseous. Then there is a group which are not resolvable, some of which give a continuous spectrum and others a gaseous spectrum.

I have thus endeavoured, however imperfectly I have succeeded, but still so far as time and opportunity admitted, to bring before you some of these spectrum discoveries. The more we pursue studies of this matter the more is the mind carried forward with the desire for further knowledge. Whilst thus from time to time we are permitted to get fresh glimpses into the constitution of the universe, and to trace something more of the infinite mind which has designed the whole, so should we feel the more that we are bound to use the fresh knowledge thus placed at our disposal, not for the glory of man, but, as far as may be, for the glorifying Him who made all things and upholds all things by the word of His power.

BRITISH MEDICAL ASSOCIATION.

Twenty-fifth Annual Meeting, 1867, held in Dublin.

Dr. Charles A. Cameron read a paper, in the Physiological Section, on the "*Assimilation of Gelatine.*"

The author re-opened the question of the nutritive value of gelatine. He considered that the French Commissioners on this subject had gone too far in denying the alimental value of this substance. He pointed out as strong arguments in favour of his views as to the assimilation of gelatine, the facts—that that substance when largely used as food passes off in the form of urea, and is not found in the fæces. As gelatine passes rapidly from the stomach into the circulating fluids of the body, and becomes decomposed therein, it is impossible not to assign to it some useful functions. The author then described some experiments which he had made on this subject. He employed the dog and the white mouse, the latter animal being peculiarly well-adapted for such experiments. He found that these animals could not live on food consisting of gelatine, fat, butter, sugar, starch, and mineral substances. This was the result the author had expected, for the following reasons. In the nitrogenous portion of animals there exist sensible amounts of organic sulphur and phosphorous compounds ("alloxidic"). Gelatine does not include these elements, and is therefore incapable of forming muscles and nerves. The addition of mineral sulphates and phosphates to gelatine does not increase its nutritive value, because animals are not endowed with the power of organizing mineral sulphur and phosphorus, although this function is the attribute of plants.

In some of the fats of the brain and nervous tissue generally there are notable proportions of organic and unoxidised phosphorus and sulphur. By combining these phosphorised and sulphuretted fats with gelatine, and adding thereto some other non-nitrogenous and mineral substances, Dr. Cameron formed a food on which mice lived for forty-two days in a very healthy state, although the said food was deficient in albumen and fibrin.

Taken under ordinary circumstances, gelatine, according to the author, is most probably employed as a calorifacient, and perhaps also as a source of motive power. In an agreeable form it was a food very much relished by invalids, and there was a good reason underlying the popular practice of making gelatine a common article of food.

Mr. Tichborne read a paper, in the same section, on the "*Organic Matter in Potable Water.*"

He dwelt at some length upon the difficulties attendant upon water analyses. The point of difficulty in the examination of potable waters being not so much their quantitative as the qualitative examination—particularly as regards their organic constituents—you may have a water rich in organic matter yet harmless, or a water containing but a minimum of organic matter of the most deleterious nature. He remarked that all the following points in an analysis had an important bearing upon the state of the organic matter, viz. nitrates, nitrites, ammonia, total nitrogen, odour, taste, colour, hardness, chlorides, iron, gases dissolved, microscopic examination, etc. The author gave a quick method for estimating the nitrites in potable water, based on the conversion by heat of nitrite of ammonium into nitrogen and water—the loss being estimated by a volumetric solution of permanganate of potassium. Mr. Tichborne then described a tube or convenient instrument for viewing the colour of water, and for examining the state of oxidation of the iron salts or matter of some importance in connection with the organic matter, and a point not so easy to determine in very diluted state—as the microscope magnifies the form, so this instrument magnifies the colour, or colour tests, so as to be recognisable to the eye. When the iron bears any *considerable proportion* to the organic matter, very little of the latter will be found (if we except ammonia), providing the iron is in the state of a ferric salt. If, however, the iron is present as a ferrous salt, it will be found to have exerted little or no influence on the organic matter, and frequently such waters (except chalybeate springs) will be found to contain large quantities of soluble organic matter.

The author remarked that it had been stated that charcoal that had been used some time, so far from taking from the water the organic matter, gives up again a certain amount. That water on analysis before and after passing through old charcoal was more contaminated with organic matter, after having been passed through the said filtering medium. The *modus operandi*, however, by which charcoal acts, is not so much by any attractive power that it possesses,—that is to say, it does not absorb the mass of the organic matter, but acts as one of the most powerful oxidisers. The oxygen condensed within the charcoal acting more energetically than the available oxygen we can apply in the form of permanganate of potassium. A charcoal filter was found from actual observations to work wonderfully well, and to retain its vitality for a long period, with the following provisions. That the water passed through it did not contain a very large percentage of organic matter. That it was not continuously at work,—that is to say, that the charcoal was exposed to the atmospheric oxygen (with as little of the dust as possible) the better part of each twenty-four hours. That the water was passed through a filtering medium before it came in contact with the charcoal. If not, the charcoal acted as a mechanical recipient to the insoluble organic matter, which at last accumulates to such an extent as to enter into a state of fermentative change; the activity of the charcoal being by this time exhausted, or at least only sufficient to supply a minimum of oxygen, would only assist such a decomposition. This state of the case would be simply the putrefaction of a mass of organic matter independent of the charcoal, not the rendering back from the charcoal of something it had absorbed from the water.

Mr. Tichborne exhibited a table of the action of permanganate of potassium upon organic substances, which illustrated the worthlessness of that substance as a measure of fermentable matter. He also stated that peroxide of hydrogen, if it could be procured *pure*, and at a reasonable price, might be used with advantage, for the purification of water.

The only other papers read at these meetings, possessing a chemical bearing, were: Dr. Protheroe Smith "*On the Mode of Detecting Impurities in Tetrachloride of Carbon,*" and Dr. O'Leary "*On the Thermal Value of Food,*" *etc.*

ACADEMY OF SCIENCES.

JULY 22, 1867.

(FROM OUR OWN CORRESPONDENT.)

Sir D. Brewster on liquid films and figures of equilibrium.—Storms exceptionally caused.—Proportion of iodine in mineral waters.—Classification of meteorites.—Discovery of universal gravitation, letters of Pascal to Boyle; Discussion; Newton and Pascal in correspondence.

SIR DAVID BREWSTER addressed copies of his pamphlets (reprinted frm the Roʎoal Sietocy of Edinburgh) on the colours of thin liquid films and their figures of equilibrium, of which we have already published the analysis. The illustrious professor, foreign associate of our Academy of Sciences, at the age of 85 years, retains his memory so fresh and bright that the two memoirs in question seem to be the offspring of a youthful mind.

M. Fournet of Lyons addressed a note on the exceptional storms caused by the south-west winds.

We understood, vaguely, that there were communications on geological sections of the Alençon railway—of a memoir by M. Thibaut on inundations—of an efficacious method of treating croup, by Dr. Abièlle—of researches on electricity by M. Girard—of a means of ascertaining the proportion of iodine contained in mineral waters and in alkaline salts—of a memoir by M. Humbert on the resistance of a voltaic pile, etc.

M. Daubree read the second part of his memoirs on the classification adopted for the collection of meteorites in the Museum of Natural History. His principal divisions of solid and coherent meteorites are as follows:—1st Class: *Siderites*—meteors containing iron in a metallic state; subdivision, containing stony substances. 1. *Holosiderites*—Meteoric iron properly so called; second subdivision containing iron and stony substances. 2nd Group: *Syssiderites*—iron in the form of a continuous mass. 3rd Group: *Sporadosiderites*—iron in the form of disseminated grains; 1. Sub-Group of sporadosiderites, *Polysiderites*, when the quantity is considerable. 2. Sub-group: *Oligosiderites*, containing a small quantity of iron. 3. Sub-group: *Cryptosiderites* in which the iron is invisible to the eye. 3rd Class: *Asiderites.* 4th Class: *Asiderates.*

M. Le Verrier called upon M. Chasles relative to the letters and notes of Pascal printed in the Comptes Rendus, and of which we give, before resuming this long discussion, a few important passages: —8th May, 1652, Pascal to Boyle—"J'ay pour le prouver un bon nombre d'observations de toutes sortes dont personne m'a encore parlé, et partant en connaissance, tant sur l'attraction et de ses lois avec les phenomènes. Je viens vous en faire part. Vous trouverez cijoint les experiences, au nombre de plus de cinquante.

"PASCAL."

2 Sept., 1654 or 1655.—Again to Boyle.—"Dans les mouvements celestes, la force agissant en raison directe des masses et en raison inverse du quarré de la distance suffit à tout, et fournit des raisons pour expliquer toutes les grandes revolutions qui animent l'univers. Rien n'est si bon selon moy; mais quand il s'agit des phenomènes sublunaires, de ces effets que nous voyons de plus près et dont l'examen nous est plus facile, la vertu attractive est un Protée qui change souvent de forme. Les rochers et les montagnes ne donnent aucun signe sensible d'attraction. C'est, dit-on, que ces petites attractions particulières sont comme absorbées par celles du globe terrestre, qui est infinement plus grands.

"PASCAL."

Note to Boyle.—"Le corps en vertu de la tendance au mouvement que l'attraction lui imprime est capable de parcourir un espace donné dans un temps donné. La vitesse initielle sera donc proportionelle a l'intensité de l'effort ou de la tendance imprimée par la puissance attractive; et cette intensité sera elle-même proportionelle à la masse attirante a egale distance, et (à) differentes distances, comme la masse attirante divisée par les quarrés de ces distances.

"Les observations atronomiques apprennent que toutes les planètes se mouvent dans une courbe autour du Soleil, et qu'elles sont accelérées dans leur movement à mesure qu'elles approchent de ce globe, et qu'elles sont retardèes à proportion qu'elles s'en eloignent, tellement qu'un rayon tiré de ces planètes au Soleil décrit des aires ou des espaces égaux en temps égaux.

"PASCAL."

"J'ai dit que la force de projection qu'on nomme force centrifuge varie continuellement, parce que l'attraction est plus ou moins grande suivant que les planètes s'approchent ou s'éloignent du soleil. Pour concevoir comment cette révolution s'opère, supposons qu'une planète soit à la partie de son orbite (ou de l'ellipse qu'elle parcourt) la plus proche du soleil, la force attractive est dans cet état plus grande que dans toute autre situation, à proportion que le quarré de la distance est moindre. Elle devroit donc faire tomber la planète sur le soleil, mais la force centrifuge produite par le mouvement circulaire autour du soleil augmente en plus grande proportion.

"PASCAL."

"La puissance qui agit sur une planète plus proche du soleil est ordinairement plus grande que celle qui agit sur une planète plus éloignée, tant parce qu'elle se meut avec plus de vitesse qu'à cause que son orbite est moindre et qu'elle à plus de courbure. En comparant les mouvements des planètes, on trouve que la vitesse d'une planète plus proche est plus grande que la vitesse d'une planète plus éloignée, en raison de la racine quarrée du nombre qui exprime la plus grande distance à la racine quarrée de celuy qui exprime la moindre distance.

"PASCAL."

"On peut conjecturer et même inférer qu'il n'y a une puissance semblable à la gravité des corps pesants sur la terre, qui s'étend du soleil à toutes les distances et diminue constamment . . . Le même principe de la gravité doit avoir lieu dans les satellites qui circulent autour de la terre, de Jupiter et de Saturne. . . . Car ils ne pourroient avoir un mouvement aussi régulier qu'ils ont s'ils n'étoient assujettis a l'action de la mesme puissance, etc.

"PASCAL."

The intimate acquaintance of Newton with Pascal is proved by letters written by Newton in most excellent French. Newton was then only eleven years old

The question that M. Leverrier at last put forth, after endless circumlocution, was this:—Is M. Chasles in possession of letters and notes which demonstrate undoubtedly that Pascal knew, not only the laws, but the demonstration of universal gravitation? M. Chasles hesitated to answer, because he would wait till the termination of the discussion of that which he had already spoken of to the Academy; he consented, however, to acknowledge that it results from the authentic autographs in his possession that Pascal had determined centrifugal force in the curvilinear motion of the planet; thus, this determination implies the demonstration of the elliptical nature of the curve described under the influence of attraction.

MM. Duhamel, Elie de Beaumont, Pouillet, Faye, Leverrier and Chasles took part successively in the discussion, but on subjects not bearing directly on the question. M. Duhamel supported the adversaries of Newton; he could never understand how he gave, at so late a period, the mathematical expression of the law of gravitation in inverse proportion of the square of the distance. By replacing the ellipse by its osculating circle, he had early found the geometrical expression of the attraction, but it was necessary to deduce from synthetic considerations the value of the radius of curvature of an ellipse, which he could not do later. This geometric determination is very remarkable, and we shall shortly give further accounts of it.

It was well seen with what care M. Chasles avoided pronouncing the name of Newton in his paper. It is not generally known that when Newton was only fourteen years old, Pascal was in correspondence with Newton, and it was at his advice that Mrs. Newton sent her son to Cambridge. This unexpected announcement is most important, especially when these extraordinary documents prove that Pascal was aware of the laws of universal gravitation. Certainly M. Chasles ought to be left at full leisure to prepare his dissertation, which is waited for impatiently by the scientific world.

M. Chevreul laid on the table two pamphlets relative to Natural History and the Gobelins; the first is a most complete work describing the physical, chemical, and organic properties and relations of all bodies.

JULY 29, 1867.

Pascal's letters forgeries.—Rain-fall in Alsatia.—Experiments on Induction currents.—Surgical instruments from Pompeii.

THE Abbé Zantadeschi presented a copy of a work on the climate of Catania, the conclusions of which are that this country is one of the spots in Italy where the climate is most mild. and it is exactly the place where persons suffering from pulmonary complaints should be sent.

M. Faugére, sub-director of the Minister of Foreign Affairs, who had devoted his life to the subjects of the illustrious Pascal, and the history of his family, who had the good fortune to discover the several precious unpublished documents entitled "Penseés, fragments et lettres de Blaise Pascal," was struck with the account of the letters and notes presented and given to the Academy by M. Chasles; he wished to see these surprising autographs, and was convinced that the signature of the letters deposited by M. Chasles is not that of Pascal, but that they are simply forgeries. He requested the Academy to appoint a commission for as scrupulously as possible inquiring into the authenticity of these documents.

M. Chasles replied that he had no doubt whatever on the validity of the letters and notes presented by him, and that he hailed with pleasure the appointment of the commission demanded by M. Faugére. The members are MM. Chevreuil, president; Delaunay, V.P.; Elie de Beaumont and Coste, secretaries; Chasles, Duhamel, Pouillet, Faye, and Leverrier. M. Chasles disputed the assertion of M. Duhamel, "In admitting the authenticity of the letters deposited by M. Chasles, and supposing even that they had been published before the *Principia*, they would not give the right of priority to Pascal for the law of universal gravitation. The glory will ever rest with Newton." M. Chasles maintains, on the contrary, that the glory of the discovery, and the demonstration of universal attraction proportional to the masses is in the inverse ratio of the distance, belongs to the immortal Pascal. He proved by calling to mind the following of the letters and notes of the illustrious philosopher, and which will create a profound sensation in England.

M. Becquerel presented a note on the temperature of water currents, by M. Ch. Grad.

In two former communications he gave his researches on the fall of rain in Alsatia, and the relations which exist between the flow of water in the Ill, and the rain-fall in its basin; to-day he submitted the result of the running waters in the same region. These observations, repeated twice a day, at 7 A.M. and 4 P.M., were made principally on the Fecht. The Fecht is a sort of torrential river, taking rise in Hautes Vosges at a height of 3,300 feet above the level of the sea. The following are the comparisons made between the temperature of the water and that of the air:—The mean temperature of the water from July, 1866, to June, 1867, was found to be 10°·5 C. inferior, by 0°·8, that of the air at Turckheim. The difference between the temperature, maxima and minima, of the year was 23°·7. The greatest variation was during the month of May, 13°·3, and the greatest diurnal variation, 7°·6, occurred the 14th July. The amplitude of the oscillations is less for water than for air; the temperature of water attains its diurnal maximum and minimum only after the maximum and minimum of the air have been reached. In summer the rains lessen the temperature of the Fecht, and in winter it is raised. Also the range of variations was found to be more decided in summer than in winter; weaker under an overcast sky than in a clear one, and it becomes more pronounced according as we recede from the sources, with the increase of volume of the water-course. This last observation confirms those of M. A. Bertin, on the temperature of the Ill at Strasbourg, and the Lower Rhine at the Kehl Bridge, as shown by the following results:—During the year 1858 to 1859, the average temperature of the air at Strasbourg was 10°·2 C; that at Kehl Bridge 10°·5; the water of the Rhine at Kehl Bridge, 10°·9; the Ill at Strasbourg, 11°·2. These results give to the Ill and the Rhine a higher temperature than that of the Fecht; and this general law can be deduced, that in the *same region* the temperature of running waters increases with their volume.

M. Regnault presented, in the name of M. Blaserna, professor of the University of Palermo, results of experiments on the passage of induction currents. His conclusions are the following:—1. The time elapsed between the closing or the rupture of the circuit and the apparition of the current of induction, or the attraction of the armature for the bobbin of induction is inappreciable, less than the fiftieth part of a second. 2. The current of induction, feeble at its commencement, increases little by little, then diminishes, and is extinguished in an interval difficult to determine.

M. Elie de Beaumont gave official notice of the election of M. Wurtz in place of M. Pelouze. late master of the Paris Mint, and called upon him to take his chair.

Dr. Scoutteten, principal physician of the army of France, read a paper on the surgical instruments, probes, specula, etc., found in the ruins of Pompeii. He mentioned, especially, one instrument, a probe, presented by Gallien to a magistrate named Erastitrate, and which seems preferable, in a practical point of view, to those new in use.

AUGUST 5, 1867.

Fall of Aerolites.—Ozonometry.—Oxide of Thallium a Test for Ozone—Theory for Solar Spots.—Wax of the Fig Cochineal.—Moulting of Fishes.

THE minister of public instruction transmitted, on behalf of the Algerian Government, several documents relative to the fall of aerolites which took place on the 9th of May, 1866, preceded by the appearance of a *bolide*, or meteor, which exploded with very loud reports.

Dr. Berigny presented a memoir on ozonometry, being a *resumé* of observations made during a period of nine consecutive years with iodized paper much more sensitive than that of Schönbein, and a scale of shades drawn up in concert with M. Salleron. The following are the principal results obtained at Versailles; the month of May is that during which the maxima are absolute, in November the absolute minima take place. At the equinoctial periods, March and September, ozone attains its relative maxima. The importance of the months is ranged in the following progressive order: May, March, April, June, August, July, September, January, December, October, February, and November. The comparison of the ozonometric curves with the meteorological charts of the observatory show that a maximum of ozone corresponds with the presence of a storm in Europe, or the Atlantic, or on the coasts of France and England. Certain minima follow the same law; but then it happens always that the storm is thrown back towards the south before reaching the meridian of Paris, and that it traverses Spain and the Pyrenees to extend itself over the Mediterranean. The coloration is generally very strong when the storm traverses France and England; it is also produced when it passes very high in the north. It varies with the intensity of the atmospheric movement, and with the distance at which the centre of this movement passes.

Dr. Besigny laid on the table a copy of the researches made on ozone, read by M. Schönbein at one of the meetings of the Scientific Association of France, held at Metz. The following is an extract:—Ordinary oxygen is without action upon the protoxide of thallium, while ozonized oxygen combines rapidly with this oxide so as to form the peroxide of thallium, which is brown. Paper steeped in a solution of oxide of thallium and exposed to free air, would be an excellent ozonometric paper if the carbonic acid of the air did not transform the oxide into carbonate, which passes more slowly to the state of peroxide, and blackens with difficulty under circumstances where strips of paper, iodized and starched, become coloured at the end of a few minutes in an atmosphere which contains a 1-2,000,000th part of ozone. The comparison between the two papers has at least the advantage of proving that the coloration of the iodized paper is really produced by the atmospheric ozone.

In an answer made by Mr. Faye to the objections urged, in April last, by M. Kirchhoff, against his theory of solar spots, he stated the question in the following terms:—"Admitting that the solar spots are simple 'daylights' (they are assuredly only cavities), in the luminous clouds which constitute the photosphere, to explain how it happens that we do not perceive through the cavity the whole body of the sun (150,000 leagues thick), the internal face of the photosphere on the opposite side of the celestial body in all its brightness." Again taking up the discussion, M. Faye calculates the tajectory of the luminous ray starting from that portion of the photosphere opposite to the eye which regards the spot, and thinks that he can prove by a very simple analysis, by supposing the obscure mass of the sun to be perfectly transparent, this portion of the photosphere would remain invisible. The reason of this is that the luminous ray would describe a spiral curve without ever coming out. Examining, then, the English theories, which pretend to explain the spots on the sun by its atmosphere, the influence or position of the planets, the intervention of cometary or meteoric matter, he demonstrated that these three causes are totally insufficient and inadmissible, inasmuch as they imply the existence round the sun of an atmosphere the thickness of which is one-third of the solar radius.

M. Blanchard presented a note from M. Targioni Tozzetti, professor at Florence, on the wax produced by the fig cochineal (*coccus coricæ*), which contains half its weight of ceroline, and can be abundantly procured and used in the industrial arts.

M. Blanchard also presented a note on the moulting of fishes, by M. Baudelot. Tubercules are often observed on the skin of fishes, accompanied by the falling off of the scales; these were sometimes considered a characteristic of a new species of fish. M. Baudelot has found that they are periodical, and are to be found in certain seasons of the year, thus constituting a true moulting.

NOTICES OF BOOKS.

Observations upon a New and Simple Process for the Preservation of Meat, Fish, Poultry, and other Varieties of Animal Food. London: Simpkin, Marshall, & Co.

A NEW process for the preservation of meat by means of a solution of bisulphite of calcium, has been lately patented by Messrs. Medlock and Bailey; and the pamphlet we are about to discuss has been written with the object of describing the process and its application. It is somewhat unfortunate that the writer adopts the style usually displayed in the commencement of such descriptive pamphlets. He proves satisfactorily to himself that all the processes hitherto employed for the purpose to which this patent is applied are lamentably defective. It is needless to mention the objections raised in each particular case, and it is much to be regretted that the author does not confine himself to a statement of the undoubted advantages possessed by the special process which he advocates, without drawing invidious comparisons.

The preservative employed by Messrs. Medlock and Bailey, is undoubtedly a very powerful one, and although its application to the purpose of preserving food may be new, the antiseptic properties of sulphite of calcium have long been recognized; it is, indeed, one of the chief components of McDougall's powder. In the patent now brought before us, however, the more soluble bisulphite is employed. This compound possesses several advantages over other sulphites, which will strike chemists at once. It is easily obtained free from sulphate, and if any sulphate should be afterwards formed by oxidation no unpleasant taste would be noticed by the consumer; these points have probably operated against the extended use of sulphite of sodium. The low equivalent of calcium is also somewhat in its favour. Messrs. W. Bailey & Sons have engaged to manufacture the bisulphite of calcium, and guarantee to deliver it absolutely pure. With regard to the results that have been obtained, as set forth in the pamphlet, they are remarkably good. The ordinary preservative solution is made as follows:—Dissolve about a pint of common salt in four gallons of clear cold water, to which add half-a-gallon of the bisulphite, and mix well: if the meat etc., to be treated is required to be preserved for a very long period, a little solution of gelatine or white of egg may be added with advantage. All kinds of meat may be kept perfectly sweet by simply soaking the joints in the above preservative solution for ten minutes, and then hanging them up, wetting them again with the solution once a day.

It is stated that beef, mutton, lobsters, etc., treated by this process, kept good for twelve days, with the temperature varying between 80° and 110° F., the original odour and flavour remaining unimpaired at the end of the time. In twenty-six hours portions of the same animal matter, unprepared, were absolutely putrid,

The process seems likely to prove valuable both to the public and the patentees.

Gas Manipulation. By the late HENRY BANNISTER. Enlarged by WILLIAM T. SUGG. London: Henry Sugg, 32, Henrietta Street, Covent Garden. 1867.

OUR most eminent chemical authorities have lately interested themselves so deeply, not only in the actual quality of coal-gas, but also in practical details whose consideration is necessary for understanding how impurities appear, persist and accumulate, that, as a result, gas manipulation has become a branch of study that may be called chemical jurisprudence. Thus, within a very few years, by laborious investigations of chemists, the subject of gas supply, with the impurities of gas, has been raised to a degree of accuracy equal or even superior to that of the sister subject of water supply, with its impurities. These two subjects, with histories so very different, have reached a nearly identical climax, in that the chemist and the engineer will, for the future, have nearly an equal weight of evidence to give in the witness box, on questions touching either subject. A branch of the science is thus steadily growing in importance, and we should welcome with much pleasure a short text-book on this department of chemical jurisprudence for the busy practical man.

Such a work would now, thanks to the enterprise of publishers, and the increasing number of text-books on all these subjects, be a mere matter of compilation, giving in one volume information of the most valuable character, now scattered in scores, or even hundreds of books and pamphlets, which matter, we have much reason to fear, will be quite lost to the profession if not properly secured in time.

In the absence of such a book, however, Bannister's, or rather Sugg's gas manipulation (so greatly has the original book been enlarged and improved), will for many years be a valuable text-book for the chemical jurist; this could not so justly be stated of the former edition.

With regard to some minor points, in fairness to our readers, we must make a few remarks and extracts;—thus the use of turmeric paper for testing the presence of volatile alkali, is advocated without any mention of the fallacies that attend its use; the very great superiority of red litmus paper in this respect has generally been insisted upon, especially by Mr. Bowditch. Again, for the quantitative estimation of ammonia, the decimally divided imperial liquid measure is used, which, however good in its way, has not the sanction of extensive use by chemists. With an English and French method in vogue of nearly equally extensive use, there is no room even for "a golden mean" system, as its advocates would call it. In any estimates made in legal statements, a very simple question would become infinitely involved by the necessary explanation that one cubic inch = 36·06543 septems, and that 1 litre = 2·2 deci-gallons. We think that by quoting one example, the volumetric testing by this method will be seen to be decidedly inferior to more recent methods.

"For testing ammonia by oxalic acid"—"the following solutions are required." 1. A solution of oxalic acid, 100 septems of which are equal to 10 grains of ammonia; 2. A solution of ammonia of which 100 septems contain 1 grain of ammonia. 3. Tincture of hematine; for this septem-burettes, etc., are used; the results thus obtained are not at all readily calculated either into grain or gramme measures.

In another part of the book, fluid ounces and drachms are used for volumetric purposes.

A valuable portion of the work is devoted to the question of photometry, which is most skilfully handled. Two full-paged illustrations of the photometers of Bunsen and Dr. Letheby respectively are given in white lines on a black ground, and the doctrine of irradiation as connected with luminous impressions, is very markedly illustrated on a large scale by these beautifully clear prints. 15 others engravings are also given on toned paper, equally artistically executed; and we have no hesitation in saying that this is the most perfectly illustrated scientific work that we know of, published in England.

We leave to our readers the pleasure of reading the details of the self-registering photometer, by which with the aid of photometry the varying pressure of gas may be registered during the 24 hours.

It has been named after the workers out of the idea, Messrs. Kirkham and Sugg, who acknowledge the valuable assistance rendered by Mr. Glaisher.

To those of our readers who have studied Mr. Bowditch's experiments on the value of illuminating candles, which seemed of such a convincing nature, and have remembered Dr. Frankland's remarks on the same subjects, the following extract from the preface will be of interest;

"The variations so frequently found to occur when using the standard candle in conducting experiments, are shown to be in a great measure attributable to a defective mode of application; and suggestions, based on actual practice, are offered, the adoption of which will ensure as great an approximation to the truest results as the present Parliamentary regulations will admit of."

Propriétés Desinfectants des Permanganates Alcalins. Henry Bollman Condy. Paris: J. B. Baillière et Fils. 1867.

The readers of the Chemical News doubtless remember the tenor of some remarks made in this journal under the heading, "French Academicians and English discoverers;" from our later numbers also they have learnt that Sir Isaac Newton himself is not to escape; and although we are sorry that Mr. Condy should have occasion to assert his right of priority of discovery, we congratulate him heartily at finding himself in such good company, and ourselves for this opportunity of learning the whole history of the application of the permanganates to disinfection, afforded by the necessity of publishing such a claim.

Mr. Condy observes truly, that although M. Marguerite in 1850, and MM. Bussy, Florès-Domonte, and Péan de Saint Giles still later, advocated the application of the permanganates and manganates for oxidizing purposes; they did so merely for purposes of chemical analysis; and the proof of commercial application being still unrecognized, is found in there being no exhibition of these salts at the French Exhibition of 1855. Towards the end of this year Mr. Condy first showed these disinfecting powers. We have in Appendix A the most complete verification of Mr. Condy's views from the highest authority, Professor Hofmann; this document is dated July 21, 1856. In spite of this M. Castex claimed, in 1863, from the Academy of Sciences, a recognition of his discovery of these properties. Mr. Condy thereupon, by Dr. Mitchell, addressed to the Academy a most unanswerable reply to M. Castex's claims. This called forth in reply a letter addressed to the Academy by a Dr. Blache (March 24, 1864), and this will be for some time memorable in the history of invention as an unexampled specimen of cool impertinence; we quote—

"Et puis nous ferons remarquer que ce n'est pas l'idée seule *qui fait le merite* d'un travail, surtout d'un travail qui a un but pratique; c'est la poursuite de cette idée dans les faitt . . . . M. Castex a experimenté par lui-même; il nous fais connaître des faits puisés dans sa propre pratique. Ces faits sont bien à lui. Ces faits ne sont pas ceux de M. Condy; et s'ils confirment ceux de M. Condy, tant mieux"!!

Dr. Blache admits the discovery, but disputes the full demonstration by a series of experiments, in effect, if not directly, by attributing such a series of experiments to somebody else.

The history of this case may be taken as a pattern of the flimsy way in which French chemists have lately been in the habit of making discoveries. We can discover nothing in Mr. Condy's language that shows anything but the strictest courtsey, truth, and confidence in the justice of his claim.

Elements of Chemistry, Theoretical and Practical. By William Allen Miller, M.D., LL.D., Treasurer and Vice-President of the Royal Society, Vice-President of the Chemical Society, Professor of Chemistry in King's College, London, etc., etc. Part I., Chemical Physics. 4th Edition, with additions. 1867. (Longmans.)

For the last dozen years Professor Miller's book has been the most important of English manuals of chemistry. Smaller and cheaper works have indeed very frequently supplied its place to the beginner and the non-professional student; and the advanced chemist has been constantly compelled to resort to the elaborate, though somewhat inconvenient, handbook of Gmelin. But for ordinary use by the advanced student, the manufacturer, the general reader, and the professional chemist, "Miller" has been the almost invariable guide. It is looked upon by most English chemists with a kindly regard, derived partly from familiarity, but even more from gratitude. No one can estimate the importance to the progress and spread of a science, of a well-written, lucid, and comprehensive manual. Sciences which are not so provided are sure to languish, if not in development, at any rate in popular estimation and general cultivation.

Very peculiar qualifications are necessary for the successful compilation of such a manual. The author must be a man of original genius as well as of deep and varied knowledge. He must be unprejudiced and tolerant in his judgment, able to see the fragmentary truth in two contending views, and able, also, to sift contending evidence—the amount of which is unfortunately always immense,—and, without dogmatising, to note the probabilities to which it points. And, finally, to render his labours of much avail, he must be a man of mark in his science—one whose researches and experience are sufficient to stamp his opinions with some authority. It is not good that he should be too closely bound to any one of the fleeting systems of science. He must be an exponent, not an advocate, using new theories and crude, half-proven facts with the cautious hand of one who knows how soon they may be swept away. His duty it is to write,

> "Not clinging to some ancient saw;
> Not mastered by some modern term;
> Not swift, nor slow to change, but firm
> And in its season bring the law
> That from Discussion's lip may fall—"

surrendering the most cherished of his convictions, the most habitual of his modes of expression, the moment the growing mass of scientific fact shall point it out as desirable.

It is unecessary to point out how well Professor Miller fulfils these hard conditions. There is probably no chemist in England less dogmatic in his tone of thought or less wedded to any particular system. The present edition of his "Manual" affords, we are happy to say, a most convincing proof of this, if any proof were still wanting. Just at the juncture when the interests of chemistry required it, when the revolution which began with the petty insurrection of $\Theta=16$ against $O=8$, is completing itself, and when something like consistency is once more apparent in the language of chemical journals, this new edition appears, and we find that the author, instead of endeavouring to patch up an effete doctrine, has given in his adhesion to the new, and formally ranged himself under its banners.

Every chemist knows the book so well that it would be absurd to offer more than a few passing comments upon it. The present volume, occupied almost entirely with physics, is but little changed by the alteration in nomenclature and notation. The introductory chapter has been chiefly re-written, and although the author, with characteristic caution, stops short of the extreme development of the most modern theorists, his sketch of the laws which govern the operations of chemical force is perfectly in accordance with modern doctrine, while it preserves the admirable lucidity which distinguished previous editions. As in Hofmann's little book, the term "equivalence" is used instead of "atomicity," which is decidedly barbarous, and is, moreover, open to the charge of implying more than can be proved.

The general plan of the volume has been but little altered, though a good many additions have been made to it. The section on the photographic action of light has, very wisely, been transferred from the second volume, and is a most valuable summary of the present state of knowledge upon the subject. Spectrum analysis is, of course, enlarged, and is prefaced by a useful sketch of the history of the subject. The recent researches of Dale and Gladstone, and of Landolt, upon the connection of optical properties with chemical composition, are shortly described. The wonderful results of Graham on the absorption of gases by metals have been inserted, although his last extraordinary experiment, in which hydrogen was separated from a meteorite, was not announced until the volume was in print. In the chapter on electricity we find clear descriptions of the magneto-electrical machines of Holmes and Wilde, although the curious electrical machine of Holtz is unaccountably omitted. The conclusions of the British Association committee on the standard of electrical resistance have been inserted in some detail, well warranted by their extreme importance.

The above are, we believe, the most important of the additions which distinguish this edition. Of course there are a few omissions to notice: it would be a strange thing if there were not in a work upon so wide a plan. We regret the absence of Stokes's beautiful and simple methods for the spectroscopic examination of liquids, and their extensions by Sorby, though perhaps the latter belongs more properly to microscopy. And, to select another illustration, it would surely have been well to have given some account of Balfour Stewart's striking experiment on the rotation of a disc *in vacuo*, for although its present explanation must still be regarded as hypothetical, it is in the highest degree suggestive. These, and a few more of the same kind, are, however, but specks in a most excellent work, and we cannot conclude without congratulating the author on the care and skill with which he has moulded the successive editions of his book into harmony with the rapid strides of science.

Germinal Matter and the Contact Theory. James Morris, M.D., Lond., Fellow of Univ. Coll., Lond. London: John Churchill and Sons, New Burlington Street. 1867.

The author of this small pamphlet of twenty-three pages in the first enters his plea in the following skilful manner —"Depreciation due only to baseless theories is too often extended to theory in general, but even a theory that does no more than harmonize a large number of facts, is a useful aid to further progress, and is often the means by which we arrive at a law." As a rule the largeness of the number of facts is in direct ratio to the looseness of the theory, as opposed to law. A medical theorem is then worked out *seriatim*, by what the author calls three easy steps; we may call them his axioms.

Axiom I. "Air floats with ease and for a considerable time and distance, light, and small masses of organic matter." Well-known facts are quoted for this, but a certain vagueness of expression somewhat tends to embarrass the reader, *e. g.*, "Seeds of *all sizes* sail in the air, from the thistle or taraxacum, with their parachutes of bristles, down to the smallest floated by its thread of cotton." A rigidly accurate reader might feel disposed to quibble about this statement, as is his wont; seeds of all sizes include horse-chestnut and cocoa-nut seed, and evidence of their being floated by air is still wanting.

Axiom II. Minute portions of organic matter are constantly thrown off by animals and men.

Axiom III. These are received into the body, and some pass into the lungs so as to reach the blood.

These are not to be disputed, and the theorem follows, "Light little masses from the body of one individual are constantly received by other individuals so as to reach their blood."

An interesting number of facts are in the next place cited, to show what diseases are known to be caused by essentially molecular causes, those known to be caused by organic (*i. e.* organized) agencies; thirdly, the grounds for suspecting their presence in other diseases. Dr. Beale's researches are also quoted in terms of the highest praise; "to him we owe the outline of what I conceive to be a generalization, hereafter probably to rank as a landmark in medical science." The pamphlet as a whole we esteem highly, more especially for its clear ordination of facts, and the plainly stated facts for the axioms necessary to work out a theorem. Dr. Morris is an author whom it is very easy to follow in argument, and it is a pleasure to read a pamphlet written on his plan; these good points are so much enhanced by comparison with works that now-a-day abound with theorems without axioms, based neither upon experiment with full details, nor upon high authority with references, judiciously selected.

CORRESPONDENCE.

Magnetism and Gravitation.

To the Editor of the Chemical News.

Sir,—In reply to A. D., I cannot admit that "both the induced poles of a body undergoing magnetic induction may be regarded as at the same distance from the inducing pole thereby rendering the attraction nil." The side nearest the inducing pole being attracted, and the side furthest repelled, the attraction will always predominate over the repulsion. This is true for an inch, or a foot, and why not for any distance.

When a small needle, previously magnetised, is gently laid on the surface of water so as to float thereon, it arranges itself in the magnetic meridian, although the distance of one end of it from a magnetic pole may be only a fraction of an inch more than that of the other in a total distance of several thousand miles. Again, we know that if a magnet be placed at some distance either above or below the pan of a balance, it diminishes or increases the weight of any magnetic substance placed in the pan. Also, if a magnetised needle be introduced into the pan of a balance, below which a magnet is placed, the apparent weight of the needle varies according as we arrange it with its poles similar or opposite to those of the magnet placed beneath it. The apparent weight of a magnetic substance may then be altered at pleasure, or even reduced to nothing. Thus, when a small needle is attached to the ground by thread fixed to one, or preferably, to both ends, and a horse-shoe magnet is held above it, the needle may be suspended in the air at a distance of an inch or more from the magnet, its apparent weight being thus practically reduced to nothing.

Is there anything wonderful in a magnet being able to attract substances at a distance equal to its own length? Is it not, on the contrary, a thing of common occurrence? Why then should we consider it impossible for the magnet we inhabit to attract bodies on its own surface?

In "Fownes' Chemistry" (p. 94, 9th ed.) we find the following passage:—"Of late the march of the daily variations of declination has been carefully compared with the positions of the sun as well as the moon at the corresponding period. This enquiry, suggested by General Sabine, and carried on for a number of years in several localities, has led to the remarkable result that these celestial bodies exert a definite influence upon the magnetic needle, and must therefore be considered as magnets, like the earth itself."

If, then, the moon, as a magnet, is capable of exerting a "definite influence" at a mean distance of 237,000 miles from the earth,—if the sun, as a magnet, can manifest its power at a mean distance of 94½ millions of miles from our globe, we are driven to the conclusion that magnetism is a force which like gravity itself, though of a much more feeble character, is common to all bodies existing in space, and is capable of being exerted at immense distances.

It may be said that if the celestial bodies act as magnets on each other, certain oscillations and other changes in the relative position of the various planets, etc., would be from time to time produced, which could not be explained by the action of gravity alone, in union with the centrifugal force. Such changes, indeed, compared with those produced by gravitation, would be of a minute and trifling character; and the fact, therefore, that they have not hitherto been recognised, is no proof that they do not exist.—I am, &c.

John A. R. Newlands, F.C.S.

The British Seaweed Company.

To the Editor of the Chemical News.

Sir,—There is a slight error in your correspondent's notice of our case in the Paris Exhibition, which please permit me to correct.

"No. 2 from Bardarrig is at present sold for bleaching," this should be *blacking*.

No thorough scientific examination of the acid, basic, and neutral products of the destructive distillation of seaweed has yet been made; these have been under investigation for some time, but the well-known difficulty of completely separating these interesting bodies in a state of purity has long delayed the publication of results.

I may state, however, that the products of distillation, as well as the charcoal from this source, in their chemical composition present little analogy with those of wood, peat, or coal, and can only be chemically classed with those of bone.—I am, etc.,

Edw. C. C. Stanford.

Glasgow, July 30, 1867.

Ozone.

To the Editor of the Chemical News.

Sir,—The following are the more salient points in the development of atmospheric ozone during the past three months:—

In April there was a marked period of ozone from the 4th to the 11th. Considerable amounts were present from the 1st to the 3rd, and on the 14th, 15th, and 21st. No ozone was found on the morning of the 18th, and very little on the 12th, 16th, 17th, aft. of 22nd, 23rd, 25th, and 27th to the 29th.

In May there were marked periods of ozone on the 14th, and 15th, and 25th. Considerable quantities were present on the 4th, 16th, 21st, 27th, and 28th. No ozone was found on the 10th, 20th, and 30th, and very little from the 1st to the 3rd, 6th to the 13th, 17th to the 25th, and 29th to the 31st.

In June there were two marked periods of ozone—the first from the 4th to the 8th, and the second from the 24th to the 28th. Considerable amounts were found on the 2nd, 12th, 20th, and 21st. Very little on the mornings of the 3rd, 10th, 13th, 14th, 16th, 18th, 19th, 22nd, 25th, 29th, and 30th, and throughout the day on the 27th.—I am, etc.,

Bournemouth.

Gas from Charcoal.

To the Editor of the Chemical News.

Sir,—Your correspondent "G. L.," in No. 372 of your journal, asserts that I have been anticipated by Drs. Blumstrett and Reichardt in my discovery of the fact that the gas is nitrogen which escapes from recently ignited charcoal when immersed in water,—in answer to which I would desire to advise "G. L." that a notice of the receipt of my paper appeared in your Journal for December 7, 1866. Allowing, therefore, for the length of the time required for the transmission of postal information from here to your office, it will be perceived that not only was it impossible I could acquaint myself with the researches of these chemists, but that were I so inclined, I might reasonably contend for priority of discovery.

One question I beg to be allowed to ask of "G. L.," being unable as yet to examine the periodical alluded to,—Have Drs. Blumstrett and Reichardt proved—as I have—that *incandescent* charcoal absorbs nitrogen from the air?

Thanking your correspondent for his information in regard to my paper on "Soluble Vegetable Fibre," and for his courtesy throughout, but taking exception to the application of such terms as innumerable and exhaustive to the description of the researches of *any one*, however distinguished.—I am, etc.,

William Skey.

Wellington, New Zealand, May 17, 1867.

Preservation of Food.

To the Editor of the Chemical News.

Sir,—In reference to our pamphlet upon the preservation of food, will you permit us to state that with the mass of evidence at our disposal we could readily have shown a long list of the so-called "preservative processes" which have proved utter failures, and could have conclusively exhibited the causes of their non-success, but such a course would have necessitated the mention of numbers, dates, and names, together with comparisons which might possibly have been considered invidious, and we preferred, while giving the public much general information relating to what has hitherto been attempted in meat preservation, to keep out of the treatise anything likely to be considered personal, or to give offence.

We beg to draw your attention to the sixth edition of the pamphlet, containing much new matter, and to remark that the practical success of Medlock and Bailey's new patent process, as evidenced by the results obtained by various well-known metropolitan butchers, meat-salesmen, fishmongers, etc., has been quite beyond our expectation for the short period that has elapsed. The Canadian experiments were conducted by Mr. Collett, and those in this country, under the superintendence of Dr. Henry Medlock, and Mr. Wentworth Scott.—We are, etc.,

William Bailey and Son.

Remarks on the Earth's Density.

To the Editor of the Chemical News.

Sir,—My attention has again been directed to the difference existing between the earth's density and the mean specific gravity of the minerals constituting its crust, by the following paragraph, occurring in a recent lecture by Mr. T. Sterry Hunt:—"We may suppose an arrangement of the condensed matters at the centre (of the earth) according to their respective specific gravities, and thus the fact that the density of the earth as a whole is about twice the mean density of the matters which form its solid surface."

On the same subject, W. R. Grove, Esq., in his address to the British Association, 1866, makes the following remarks:—"Surprise has often been expressed that while the mean specific gravity of the globe is from five to six times that of water, the mean specific gravity of the crust is barely half as great. It has long seemed to me that there is no ground for wonder here. The exterior of our planet is to a considerable depth oxidated; the interior is in all probability free from oxygen, and whatever bodies exist there, are in a reduced or deoxidated state; if so, their specific gravity must be higher (?) than that of their oxides, chlorides, etc."

This theory of Mr. Grove, although plausible, is scarcely satisfactory, as it will be seen that many of the substances which go to form the great bulk of the earth's crust, are actually lower in specific gravity as metals than they are when oxidised; while others differ but little in density whether as metals or oxides. The metals whose densities are much lower than their oxides are the metals which form but a small proportion of the earth's crust, and the oxidation or deoxidation of which could make but a trifling difference in our earth's density. Any such difference would be more than counteracted by the opposite tendency of those substances, which constitute the great bulk of the earth's crust, as shown in the following table:—

Metals	Sp. gr.	Oxides.	Sp. gr.
Silicon........	2·49	Silica.........	2·66
Calcium	1·57	Lime	3·08
Magnesium....	1·74	Magnesia	3·40
Aluminium....	2·56	Alumina*	4·00
Sodium	0·97	Soda..........	2·00
Barium	1·50	Baryta	4·00
Potassium.....	0·86	Potassa	2·10
Strontium.....	2·50	Strontia.......	3·90

These examples prove that supposing the earth, beneath the crust to which we have access, to consist of the same metals as above, but in an unoxidised state, the density of the earth would actually be less than the specific gravity indicated by an average of the minerals existing on the surface. Unless, indeed, a far greater proportion of the heavier metals exist in the interior of the earth than on its surface. That the heavy metals do exist in much greater proportion towards the centre of the earth I think is undoubtedly the case, and the only means of solving the difficulty.

During the cooling down of the molten planet, the heaviest metals would naturally tend towards the centre, and hence if we take a table of specific gravities of the metals, we find a singular relationship to exist between the *density* and *scarcity* of a metal.

Thus we find platinum and gold to stand almost at the head of the list in point of density and scarcity, while aluminium, calcium, magnesium, etc., stand conspicuous for their great abundance, and for the lowness of their specific gravities. The metals mercury, zinc, lead, etc., may appear at first sight not to fit in with this supposed law, but when we take into account either their ready volatility or their avidity for sulphur or oxygen, as the case may be, their comparative abundance at the earth's surface may be explained notwithstanding their high densities. For instance, mercury and zinc would be among the very last of the solid substances, volatilized by the earth's heat, to condense; and would in all probability come into contact with large quantities of sulphur vapor, and would naturally take that form in which we find these metals most abundantly.

Another exceptional circumstance may be instanced as operating against the tendency of the metals to follow this law of specific gravities, in the case of iron and tin. Iron has a sp. gr. of 7·8 while tin is only 7·2. The apparent sequence to this, according to the foregoing argument, would be that tin should be more plentiful than iron. We must here again, however, take into account the contingent circumstance that iron is much more readily oxidized than tin, and when once brought into that state has the low sp. gr. of 4 to 5. This will account for the fact that iron, notwithstanding its higher sp. gr. than tin, is much more abundant at the earth's surface than tin. These I give only as examples of the exceptional circumstances that require to be considered in framing the general proposition that *the scarcity of a metal is in the ratio of its density.*

These considerations seem to me to point distinctly to the presence of the heavier metals in much greater abundance in the interior of the earth than at its surface, and especially when taken in conjunction with the fact that the earth has a density twice as great as the minerals of which its crust is composed, and that notwithstanding the probability that it contains many great cavities filled with water or gases.—I am, etc.,

John Sutherland.

Glasgow.

Gas Absorbed by Charcoal.

To the Editor of the Chemical News.

Sir,—Your correspondent from New Zealand, Mr. William Skey, asks me, in No. 400 of the Chemical News (*Amer. Reprint, Oct.* 1867, p. 195) whether Drs. Blumtritt and Reichardt have proved—as he has—that *incandescent* charcoal absorbs nitrogen from the air?

They certainly have done so; their researches extend to a great many varieties of charcoal, both old and freshly ignited, and contain many full analyses of gas. The date of the first notice about them in the *Chemische Centralblatt* is September 12, 1866, and the paper is a reprint from the *Zeitschrift für Deutsche Landwirthe.* The original publication must, therefore, be somewhat older, especially as the *Centralblatt* is generally several months behind; but at all events their priority of publication to Mr. Skey's communication cannot be doubted. However, it would be exceedingly unfair to say that this gentleman, living at such a distance from Europe, *could* in all probability have come across a German periodical, which would hardly have time to reach him in the interval between the publication; I expressly remarked in my letter in No. 372, that, "their paper has most likely not yet been noticed in English chemical periodicals." No one can have the slightest doubt that Mr. Skey has independently rediscovered the property of charcoal in question, although his opportunities in New Zealand could hardly allow him to extend his researches so systematically as those of the European *savants.* I am, etc.,

G. L.

August 3, 1867.

Magnetism and Gravitation.

To the Editor of the Chemical News.

Sir,—I should not trouble you with a second letter on the

---

* After being heated strongly.

above subject had not Mr. Newlands in his reply to my former note misquoted one of my sentences, and thereby entirely altered its meaning. The sentence should stand thus: "If the distance between the pole of a magnet, and a magnetic body be very considerable, compared to the size of the latter, both the induced poles may be regarded as at the same distance," etc., etc.

A careful reconsideration of this sentence may perhaps convince Mr. Newlands, that it is in perfect harmony with all examples advanced by him, and may show him, that he is confounding the merely (or at least almost exclusively) directive action of one magnet, or pole, on another magnet at a great distance, with the attraction or repulsion exerted between two opposite poles. Thus, a small magnetized needle, when floated on water, places itself in the direction of the magnetic meridian; but why, if it does so by virtue of the superior attraction of the North pole, does it not also move in the direction of such pole? Does not the very fact of its remaining at rest in the direction of the meridian prove that the two forces of attraction and repulsion are sensibly equal? I would, in conclusion, recommend Mr. Newlands to make the following calculation: What is the difference between the forces of attraction and repulsion exerted on the poles of a magnetic needle 1 inch long by a magnetic pole several thousand miles distant, the needle pointing towards such pole? If, after having performed this calculation, according to the well-known law that the force of attraction or repulsion varies inversely as the square of the distance, he still believes that such difference may be a measurable amount, why—I hope that he will soon furnish the world with a description of the instrument by means of which he thinks to accomplish it.—I am, &c.,

A. D.

Commercial Analyses.

To the Editor of the Chemical News.

Sir,—Some months ago we heard a little on this matter in your columns. Are we always to be annoyed by these discrepancies? I have just incurred two fees to two separate chemists of large experience in analysing artificial manures, one "high" and the other "low." These two gentlemen have operated on portions of the same fairly drawn sample of superphosphate; the difference between them is only seven per cent.! As a seller, of course I shall believe the "high" analyst, and when I am purchasing goods I shall, for as obvious a reason, employ the "low" man.—I am, etc.,

Simon Simple.

Equivalence, Quantivalence, and Chemical Value in Exchange.

To the Editor of the Chemical News.

Sir,—In an able review of an excellent book (Dr. Miller's "Elements of Chemistry") published in your current number (*Amer. Reprint, Oct.,* 1867, *p.*193) I observe an error, evidently inadvertent, yet of a kind so frequently made, and tending so much to confusion of thought, on topics which it is essential to keep clear in the mind, that a few lines of your valuable space may not, I think, be misapplied in its correction.

In the absence of my friend Dr. Hofmann, this duty devolves, I feel, upon me; because the error in question consists in the misquotation of a term proposed by us, in lieu of the vague, and, as your critic justly calls it, "barbarous" expression *atomicity*. The substituted appellation is not, as your reviewer writes (doubtless by a mere slip of the pen), "*equivalence*," but "*quantivalence*."

As *both* these expressions are retained by us, each having, in your view, its special scientific value, and only the meaningless word "atomicity" being abandoned, it is absolutely essential to philosophical precision that the two words in question should be scrupulously employed, each only in its peculiar sense, as contra-distinguished from the appointed meaning of the other.

Now, the term "equivalence" is set apart to denote the *molecule-forming* power of an element, while "quantivalence" is expressly reserved to signify its *atom-fixing* capacity.

Both these are essentially ponderal values—capable of being numerically expressed as combining-weights, in terms of the same standard unit, viz., $H=1$.

The molecule-forming power of any element corresponds with the minimum-weight thereof, relatively to hydrogen as unity, capable of taking part in the formation of a compound molecule.

The atom-fixing capacity of any element is proportional to the minimum-weight thereof capable of engaging, or conversely, of expelling and replacing, one standard atom; $H=1$ being the standard.

The former of these two values constitutes, for each element, its *equivalent*, in the ordinary acceptation of the word, which is synonomous with *atom-weight*, and *combining number*. It will be remembered that, for the volatile elements, these equivalents correspond (*exceptis excipiendis*) to the respective *gas-volume-weights*, or, *vapour-densities*, relatively to hydrogen taken as unity.

The latter of the two values, as I have elsewhere pointed out, might properly be represented, for each element, by attaching to it a second ponderal equivalent, or representative number, most frequently a fraction of the former,—a moiety, a third, or a fourth,—to denote the smallest quantity by weight capable of fixing, or replacing one standard atom.

This mode of notation would give us two parallel sets of minimum-weights, or combining numbers, each element possessing a pair; and the two being distinguishable, in most cases, as the *major* and *minor* equivalent.

I say "in most cases" because, for chlorine and its congeners, the two equivalents would coincide.

These duplicate equivalents, for the typical elements, would be, respectively, in terms of hydrogen as unity:—

	Major.	Minor.
For oxygen	16	8
" nitrogen	14	4·66
" carbon	12	3

while, for chlorine, 35·5 would represent both values.

It is, however, obvious, that the extension of such a duplicate system to 62 or more elementary bodies, would severely tax the memory and the attention (faculties of sadly limited scope, always to be most studiously husbanded), besides also seriously impairing the succinctness of the symbolic notation, so invaluable as our chemical "short-hand."

This short-hand, as commonly practised, represents each element by its initial letter, with which we associate, by a comparatively easy habit of the memory, its molecule-forming minimum-weight, or ordinary combining equivalent.

The symbol, so far prepared, is ready to have engrafted on it the further conception of *quantivalence*; which we can now exactly define.

"Quantivalence" is the atom-fixing power of the respective elements, denoted, for each typical group, by a special coefficient, whereof the index is attached, for each member of the group, to the initial letter with which is associated its name and ordinary equivalent number; the result being an exceedingly concise symbol, embodying, together with a Name, two distinct conceptions of chemical Value, with their respective Quantities.

As all the simple bodies fall naturally, in respect of their quantivalence, into four typical groups, headed respectively by the four elements cited above, the members of each group, how different soever their molecule-forming weights, correspond with each other as *uni*valent, *bi*valent, *tri*valent, or *quadri*valent, in their atom-satisfying relations.

We have only, therefore, to bear in mind this easily-remembered fourfold classification, with its simple quantivalential indices (dashes or Roman numerals at choice), in order to have constantly at hand for use all the information that the long lists of duplicate equivalents, so burdensome to the memory, must otherwise have been employed to supply.

The disburdenment of memory, and the terseness of symbolisation, thus simply attained, acquire additional value from the happy circumstance that the atom-fixing and volume-condensing powers of the elements advance *pari passu*; so that, (*exceptis excipiendis* once again) the coefficients of quantivalence serve to condense into our symbols and so to keep impressed upon our minds, besides the several ranges of facts above mentioned, this further collateral information.

Confining attention, however, to the main conceptions, distinct though allied, of equivalence and quantivalence as above defined, it is by carefully coupling these together, yet as carefully avoiding to confuse them, that we are enabled to contemplate accurately *in exchange* in its two opposite aspects, that which I have ventured to term *Specific chemical value.*

Nothing, I think, can now be clearer than that this value, so frequently misunderstood, presents itself in two aspects, and as of two kinds, accordingly as we contemplate it relatively, on the one hand, to the formation of molecules, or, in the other, to the fixation or displacement of atoms.

Adopting the first stand point, we clearly perceive that 12 parts by weight of carbon are "worth" (in financial parlance) as much as 14 of nitrogen, 16 of oxygen, 35·5 of chlorine, and so forth.

Placing ourselves at the second point of view, we as clearly see that an atom of any element in the quadrivalent group is "exchangeable at par" for four atoms of any element in the univalent group, and for three and two atoms respectively, of any element in the trivalent and bivalent groups.

I should trespass unduly on the hospitality of your valuable columns, were I to prolong these elucidations, otherwise I would fain trace out a little further the nature and consequences of these admirable relations. Among other such illustrations on which I would gladly dwell is one that I was permitted to adduce in a little book which you were pleased to notice with approval on its first appearance, and which your reviewer cites. I allude to the curious and beautiful quantivalential equipoise, or symmetry, which I have observed to prevail among the five members of the nitroxygen series.

These singular relations will be found displayed at pp. 181, *et seq.*, of the work referred to, in a diagram expressly constructed to show the characteristic feature of this remarkable series; with its central body in the self-balanced structural condition, which I have ventured to call *equiquanticity*; while its two wings form exact quantivalential counterparts, equal, though conversely reflecting one another, as each departs, by opposite grades of declension, from that self-centred archetype.

I forbear, however, from a dissertation which would tempt me too far; and, reverting to the purpose with which I set out, I beg, in conclusion, by way of summary—while acknowledging your reviewer's manifest ability—to deprecate the confusion which his *lapsus calami* (nor his alone) tends to introduce between conceptions so fundamentally distinct as those of chemical *equivalence* and *quantivalence*; signifying as they do, two opposite forms or aspects of "chemical value in exchange,"—those, namely, which we trace, respectively, in the *molecule-forming* and *atom-fixing* powers of the elements. I am, Sir, etc.,

F. O. Ward.

London, Aug., 1867.

Magnetism and Gravitation.

To the Editor of the Chemical News.

"A. D." admits that the force of magnetic attraction varies inversely as the square of the distance, and yet arrives at the singular conclusion that "when the distance between the pole of a magnet and a magnetic body is very considerable as compared to the size of the latter, the body will not be attracted." According to "A. D.'s" views, therefore, if a small particle of iron, say a single molecule, were placed at a distance of a quarter of an inch from the pole of a magnet, it would not be attracted, because the distance of a quarter of an inch would be inconceivably great compared with the length of a molecule of iron. Now, if this holds good for one molecule of iron, it holds good for any number of molecules, for the attraction of a mass may be regarded as made up of the attraction of the molecules of which it is composed. So that "A. D.'s" process of reasoning, legitimately carried out, leads to the remarkable result that a piece of iron would not be attracted by the pole of a magnet placed at the distance of a quarter of an inch from it, "which," to quote a well-known author, "is absurd."

It must be borne in mind that all I have contended for is that, theoretically speaking, just as a magnet placed under a balance increases or diminishes the apparent weight of certain substances introduced into the pan of the balance, so the weights of substances, at ordinary temperatures, on the earth's surface are not their absolutely true weights. That is to say, they are not entirely due to the force of gravitation, but a part, it may be an inconceivably small part, of the apparent weight, is due to the magnetic attraction and repulsion of the earth, and of the atmosphere by which it is surrounded.

On this point I would quote "Watts's Dictionary," vol. iii., p. 774, where we read that "a cubic metre of oxygen gas would act on a magnetic needle with the force of 54 centigrammes of iron, and a cubic metre of air with the force of 11 centigrammes of iron. The whole atmosphere is consequently equal in magnetic power to a shell of iron covering the whole earth to the thickness of 0·1 millimètre."

If bodies were weighed at high temperatures, that portion of their weight which was due to the magnetic attraction of the earth, would almost entirely disappear, and hence the weight of a given quantity of iron would be, theoretically, less if weighed at a red heat than if weighed at ordinary temperatures.—I am, etc.,

John A. R. Newlands, F.C.S.

Laboratory, 19, Great St. Helen's, E. C., Aug. 13, 1867.

Co-operative Chemical Club.

To the Editor of the Chemical News.

Sir,—It occurs to me that in these days of co-operation, it might be a good thing to form "chemical and physical clubs" in various parts of the country wherever sufficient numbers of co-operators could be obtained. There are many, I daresay, like myself engaged in commerce, manufactures, or the professions, who love science for its own sake, and from various causes cannot acquire a laboratory worthy of the name, who would gladly contribute a considerable sum yearly for the privilege of having the use of a well-stored laboratory, and intercourse with others having similar tastes and pursuing similar studies. If there were clubs of this sort in all our large towns, I am sure they would tend greatly to advance the cause of science and to spread a *correct* knowledge of it in many quarters where at present it is but little understood.

It would tend to success were some influential gentleman to bring the subject before the British Association next month, and have clubs instituted under its auspices.

If you consider this idea at all practicable, I shall be obliged by your inserting it in your widely-circulating journal.—I am, etc.

Wm. Durham.

Currie, near Edinburgh, August 17, 1867.

[The idea is excellent, and we shall be happy to give it all the support in our power.—Ed. C. N.]

Specific Gravity Problem.

To the Editor of the Chemical News.

Sir,—Your correspondent "C. H. P." may well be astonished at the reduced sp. gr. of the iron as obtained by his calculation (1·10506). He will find, however, that this lowness is due entirely to the mistake which has been allowed to creep into the method adopted for ascertaining it, and not at all to any error in the observations of *Sideros*, for, working the problem out correctly from them, the sp. gr. is obtained nearly double what it should be, if the substance is iron! The system he has adopted is a proper one, and that given in "Fownes" (in the 8th ed., page 8), for finding the sp. gr. of substances lighter than water, and may be applied to this case thus:—

Weight of iron and olivine in air.............. 50 gns.
" " " " water............ 41·8 "

Weight of water equal in bulk to iron and olivine 8·2 "

Weight of olivine in air...................... 20· "
" " " water.................... 13·75 "

Weight of water equal in bulk to olivine....... 6·25 "

Weight of water equal in bulk to olivine and iron.. 8·2 "
Weight of water equal to olivine alone......... 6·25 "

Weight of water equal in bulk to iron.......... 1·95 "

$$\frac{\text{Weight of iron in air}\ldots\ldots\ldots\ldots 30}{\text{Weight of water equal in bulk to iron}\ldots\ 1{\cdot}95} = 15{\cdot}384 =$$

= sp. gr. of the iron according to *Sideros'* proposition, which brings it to the same result as in my calculation of last week. "Lloyd" would have obtained a more accurate result also with his ingenious formula, had he not unfortunately made a mistake in multiplying 3·2 × 6·1 × 30, which is 585·6, and not 575·6. as given in his solution.

The method worked out above is accurate, but it may be interesting to consider the reasoning by which a shorter method for working out all problems of this character may be arrived at.

Supposing a body weighing A grains in air weighs in water.......... *a* grains.
And another body weighing B grains in air weighs in water.......... *b* grains.
Then the two together, " A + B. " " will weigh in water.......... *a*+*b* grains.

This is self evident, it only requires stating to be perceived, for the body which weighs A in air will displace the same bulk of water when attached to or mixed with that weighing B, that it did when by itself, and the same holds tru eof that weighing B; consequently their united action on the balance must be the sum of the weights obtained when immersed separately. This established, it will be easy to see that if a body weighing A + B in air, weighs in water *a*+*b*, and one of its components weighs A in air, and in water weighs *a*, then the second component weighing B in air, must in water weigh *b*. This last term, which is all that is wanted for obtaining the sp. gr. of the second component, being obtained by subtracting *a* from *a*+*b* in the same way that its weight in air was obtained by deducting A from A+B.

Bearing in mind the nature of the difference between those substances which are heavier and those which are lighter than water, this system becomes applicable to the solution of the interesting problem of finding the sp. gr. of substances of the latter class; all that is required being great attention in the use of the signs during the calculation.

As an example, let us take that in "Fownes," already alluded to. The problem is to find the sp. gr. of a piece of wax, this is attached to a piece of brass in order to make it sink in water.

Brass and wax together in air weigh	183·7	grns., in water		38·8
Brass alone in air weighs.........	50	"	"	44·4
Subtracting we obtain—	——			——
Wax alone in air................	133·7	"	"	−5·6

But to find the sp. gr. of a substance, we must deduct the weight in water from that obtained in air, and this difference becomes the denominator of a fraction representing the sp. gr. of the substance, and of which the enumerator is its weight in air, *i.e.*—

In this case the sp. gr. of wax =

$$\frac{133{\cdot}7}{133{\cdot}7-(5{\cdot}6)}=\frac{133{\cdot}7}{133{\cdot}7+5{\cdot}6}=\frac{133{\cdot}7}{139{\cdot}3}=0{\cdot}9598.$$

F. J. R. C.

To the Editor of the CHEMICAL NEWS.

SIR,—I send you herewith particulars of two experiments, which for my own satisfaction I have made, and in case you may think them worthy of record they are at your service.

The olivine employed was in pure translucent yellow fragments from Vesuvius—the iron being common iron wire. The sp. gr. of both were determined with care.

A. Weight of some fragments of olivine, sp. gr. 3·19, was.......................... 20·33 grs.
Do. of iron wire, sp. gr. 7·51........... 30·21 "

Consequent weight of iron + olivine was.. 50·54 "

And the sp. gr of same taken together was found to be 4·87.

Supposing the problem put in the form proposed by *Sideros*, the formula of "F. J. R. S." would give—

Weight of iron+olivine in water=
=50·54—(50·54+4·87)=...................... 40·17
Deduct waight of olivine alone in water=
=20·33—(20·33÷3·19)=...................... 13·96

Gives weight of the 30·21 grs. iron in water=...... 26·21

and 30·21+(30·21—26·21)=7·55 sp. gr. of iron required. Acing to "Lloyd's" formula.—

$$\frac{3{\cdot}19\times 4{\cdot}87\times 30{\cdot}21}{(3{\cdot}19\times 50{\cdot}54-(4{\cdot}87\times 20{\cdot}33)}=\frac{469{\cdot}321413}{62{\cdot}2155}=$$

=7·54 sp. gr. of iron required.

B. Another experiment gave following results:—

Weight of olivine of sp. gr. 3·20 employed=....... 20·32
" of iron " 7·87 " =....... 33·55

Total weight of iron+olivine being................ 53·87

The specific gravity of which conjointly was 5·09. As before "F. J. R. S's." formula gives—

Weight of iron+olivine in water=
53·87—(53·87+5·09)= .... 43·29
Deduct weight of olivine alone in water=
=20·32—(20·32+3·20)=...................... 13·97

And 33·55+(33·55—29·32)=7·93 specific gravity of iron. Or by "Lloyd's" formula—

$$\frac{3{\cdot}20\times 6{\cdot}09\times 33{\cdot}55}{(3{\cdot}2\times 53{\cdot}87)-(5{\cdot}09\times 20{\cdot}32)}=\frac{546{\cdot}46240}{69{\cdot}9552}=$$

=7·81 sp. gr. of iron.

The difference being probably in part at least due to errors of observation.

D. F.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Ammoniacal Cobalt-bases, Modes of Formation of.—C. D. Braun. 1. To a solution of cobaltic chloride or nitrate is added solid ammonic chloride and aqueous ammonia, the mixture is well shaken, plumbic peroxide added, and the whole boiled for half-an-hour. The solution then contains chiefly hexammonio-cobaltic chloride, which is precipitated in crystals on addition of chlorhydric acid.

2. A moderately strong solution of cobaltic nitrate is

well shaken with strong ammonia, pure indigo-blue (prepared according to Fritzsche's method) added, and the mixture boiled; on cooling, crystals of pentammonio-cobaltic chloride are obtained.

3. Tetrammonio-cobaltic oxychloride, hexammonio-cobaltic chloride, and aqueous ammonia, heated together under pressure, form pentammonio-chloride, according to the following equation:—

$$(A=NH_3)$$

$$3\left\{\begin{matrix}Co_2A_4\\Cl_3\end{matrix}\right\}+\left.\begin{matrix}Co_2A_4\\Cl\end{matrix}\right\}\Theta\Bigg\}\times{}_4\left.\begin{matrix}Co_2A_6\\Cl_3\end{matrix}\right\}=$$

$$=8\left.\begin{matrix}Co_2A_6\\Cl_3\end{matrix}\right\}\times\left.\begin{matrix}Co_2A_5\\Co_2A_5\end{matrix}\right\}\Theta_3$$

4. The reaction, by which from tetrammonio-oxychloride plus chlorhydric acid, is obtained hexa- and pentammonio salt (Schiff, Fremy) the author explains by the following two equations, the first representing the action of strong chlorhydric acid, the second that of diluted:—

$$\text{I.}\quad 4\left\{\left\{\begin{matrix}Co_2A_4\\Cl_3\end{matrix}\right\}+\left.\begin{matrix}Co_2A_4\\Cl\end{matrix}\right\}\Theta\right\}+2HCl=$$

$$={}_4\left.\begin{matrix}Co_2A_5\\Cl_3\end{matrix}\right\}+{}_2\left.\begin{matrix}Co_2A_6\\Cl_3\end{matrix}\right\}+Co_4\Theta_3+H_2\Theta$$

$$\text{II.}\quad 10\left\{\left\{\begin{matrix}Co_2A_4\\Cl_3\end{matrix}\right\}+\left.\begin{matrix}Co_2A_4\\Cl\end{matrix}\right\}\Theta\right\}+2HCl=$$

$$=10\left.\begin{matrix}Co_2A_6\\Cl_3\end{matrix}\right\}+3\begin{matrix}Co_2A_5\\Cl_3\end{matrix}+3Co_4\Theta_3\times H_2\Theta$$

5. Penta- and hexammonio compounds may also be obtained by acting upon xantocobaltic salts with strong ammonia, or by dissolving in them ammonic chloride and heating.—(*Ann. Chem. Pharm.*, cxlii. 50.)

Toluolsulphurous Acid.—R. Otto and O. V. Gruber. Toluolsulphurous acid ($\text{Ꞓ}_7H_8S\Theta_2$) according to these, is prepared by acting upon sulphotoluolic chloride in ethylic or benzolic solution with sodium-amalgam, and decomposing the sodic salt, thus formed, with chlorhydric acid. It crystallizes from water in large, white, rhombic plates, resembling benzoic acid; dissolves readily in alcohol, ether, or benzol; fuses at 85°, and decomposes above 100°. Exposure to moist air converts it into toluolsulphuric acid.

$$(\text{Ꞓ}_7H_8S\Theta_3)$$

The salts of toluolsulphurous acid are crystallisable and mostly soluble in hot water or alcohol; its ethylic ether is an oily liquid.

Bromine substitutes an atom of hydrogen, forming bromsulphotoluol

$$\left.\begin{matrix}\text{Ꞓ}_7H_7\\S\Theta_2\\Br\end{matrix}\right\}$$

Chlorine acts in a like manner, furnishing a chloride identical with that obtained in the ordinary manner (from phosphoric chloride and sodic sulphotoluolate), and giving with nascent hydrogen Märker's metabenzylsulphhydrate.—*Ann. Chem. Pharm.*, cxlii. 92.)

Argentic Hydrates.—C. Weltzein. Silver dissolves in a neutral solution of hydric peroxide with disengagement of oxygen and formation of a small quantity of a blueish gray precipitate. The solution contains argentous hydrate ($Ag_2=216$), and is not precipitated by sulphuretted hydrogen nor immediately by chlorhydric acid; the precipitate formed after some time consists of a mixture of chloride and metallic silver; potassic hydrate produces a dark brown precipitate. When left exposed to air, the solution assumes a reddish brown colour, and becomes turbid from silver being separated. When evaporated to dryness and extracted with water, a residue of metallic silver is left, and a solution obtained which now contains argentic hydrate ($Ag=108$). This solution has a slightly alkaline reaction, and is at once precipitated with chlorhydric acid. The nature of these reactions is shown in the following equations:—

$$\text{I.}\quad 2Ag_2+H_2\Theta_2=2HAg_2\Theta$$

$$\text{II.}\quad 2HAg_2\Theta=2HAg\Theta+Ag_2$$

$$\text{III.}\quad 2HAg_2+2HCl=2H_2\Theta+2AgCl+Ag_2.$$

(*Am. Chem. Pharm.*, cxlii. 105.)

Oxidation of Alcohol.—C. F. Schönbein. The presence of certain hydrocarbons in alcohol greatly accelerates the oxidation of the latter. When absolute alcohol is mixed with pure oil of turpentine, or a similar substance, and exposed to sunlight and atmospheric oxygen, hydric peroxide is soon formed. The nature of this process the author believes to be this:—The hydrocarbon polarises the oxygen of the air, that is to say, causes it to split up into $\overset{-}{O}$ and $\overset{+}{O}$. $\overset{-}{O}$ is used for the formation of resin, formic acid, etc., and $\overset{+}{O}$ combines on the one hand with the hydrocarbon, forming a compound similar in constitution to hydric peroxide: on the other oxidizes the alcohol, forming hydric peroxide.—(*Jour. Pr. Chem.*, c. 469).

Oil of Bitter Almonds, combination with Acetic Anhydride.—Hübner. The researches of Limpricht and of Neuhof have proved the identify of diacetic benzol, derived from benzoylic chloride and argentic acetate, with the compound obtained from chlorinated toluol; but it remained to be decided whether this compound is also identical or only isomeric with the body, first obtained by Geuther from oil of bitter almonds and acetic anhydride, the latter having been obtained as an oil, differing in that respect from the true diacetic benzol which crystallises readily. Hübner has repeated Geuther's experiments, and confirmed the latter chemist's statements, but adds, that the smallest fragment of a crystal of diacetic benzol brought in contact with the oil, causes it to crystallise immediately, and after several recrystallisations from ether it shows the melting point (44°—45°) and all other properties of diacetic benzol $\text{Ꞓ}_7H_6(\text{Ꞓ}_2H_3\Theta_2)_2$.—(*Zeitschr. Ch.* N.F. iii. 277.)

Pyrrol, Preparation and Oxidation of. — M. Goldschmidt prepares pyrrol by heating ammonic mucate with glycerine in a retort to 180°–200°. At that temperature the decomposition of the mucate into ammonic carbonate and pyrrol takes place with great regularity. This method is likewise preferable to that of dry distillation, on account of the larger quantity and superior quality of the product obtained. Pyrrol reduces argentic oxide, being converted thereby into a well defined acid which is soluble in water, alcohol, or ether, forms precipitates with silver and lead, and sublimes in needles.—(*Zeitschr. Ch.* N.F. iii. 280.)

Gallic acid, Bromo-derivatives of.—M. E. Grimaux. Bromine substitutes readily one or two atoms of hydrogen in gallic acid, forming mono- and di-bromgallic acid$=\text{Ꞓ}_7H_5Br\Theta_5$ and $\text{Ꞓ}_7H_4Br_2\Theta_5$. Both are readily soluble in boiling, sparingly in cold water, soluble in alcohol and in ether.—(*Comptes R.* lxiv. 976.)

Tantalum, Atomic Weight and Compounds of.—R. Hermann believes the composition of tantalic chloride to be $TaCl_2$, for with this assumption the vapor-density, as found by Deville, 9·6 agrees with the calculation, which requires 9·66. The atomic weight of tantalum based upon this formula is 860. To these considerations is added a compilation of all known compounds of tantalum, including several new ones, in regard to which the reader is referred to the original paper. —(*Journ. Pract. Chem.* c. 385.)

Toluol, Chloro-derivatives of.—O. Pieper. Toluol, saturated with chlorine, separates on standing crystals of the composition $\text{Ꞓ}_7H_8Cl_8$. They fuse at 150°, are insoluble in water, sparingly soluble in alcohol, more so in ether, but they dissolve readily in carbonic bisulphide. Sodic hydrate in alcoholic solution decomposes the new compound readily at 110°, and on adding water to the product of decomposition a brown oil separates, the aqueous solution containing small quantities of an acid which seems to be dichlordracylic acid, $Ꞓ_7H_4Cl_2\Theta_2$. The oil after purification is colourless, distils at 280°—290°, and has the composition $Ꞓ_7H_4Cl_4$.—(*Ann. Chem. Pharm.* cxlii. 304.)

Specular Iron made at Biber (Hepia), and used, with great success, for the production of cast steel cannons, being dissolved by electrolysis in hydrochloric acid, was found to contain (according to Bagh) the following substances:—

Carbon	3·758
Iron	87·997
Manganese	6·555
Phosphorus	0·578
Silicon	0·497
Sulphur	0·171
Calcium	0·127
Copper	0·120
Arsenic	0·118
Magnesium	0·052
Antimony	0·027
Silver, lead, bismuth,	trace.

—(*Ann. d. Chem. u. Pharm*, bd. 140, p. 180.)

Blast Furnace.—To increase the production of iron blast furnaces six-fold, Morgan gives them greater dimensions; for instance, 9½ métres in diameter, blowing into the furnace by 12 tuyeres. A hollow cone is besides constructed in the middle part of the bottom of the furnace, by means of which a blast is also introduced into the furnace.—*Revus Univers. X.* ann., 4 livr., p. 62.

Influence of a Current of Gas on the Decomposition of Compounds.—D. Gernez. When a current of an indifferent gas, as nitrogen, hydrogen, or air, passes through a solution of baric, calcic, or potassic bicarbonate, carbonic acid is given off; alcalic sulphhydrates under these conditions lose sulphuretted hydrogen, and acid sulphites and acetates are converted into neutral salts. These phenomena of decomposition are considered due to dissociation.—(*Comptes R.* lxiv. 606.)

Thallium-amalgam.—J. Regnauld. Thallium combines with mercury with evolution of heat, and the amalgam is electro-negative compared with thallium; this is a further proof of the fact that, whenever a metal dissolves in mercury and heat is given off, the metal is electro-positive in comparison with the amalgam.—(*Comptes R.* lxiv. 611.)

Propyle-benzol, Action of Bromine on.—E. Meusel. The action of bromine on cumol at ordinary temperature gives rise to the formation of two substitution-compounds, monobromcumol $Ꞓ_9H_{11}Br$, boiling between 218° and 220°, and a crystalline compound of the composition $Ꞓ_9H_7Br_5$, melting at 99°—100°. At high temperatures and in presence of water an acid has been obtained which has the composition of dibrombenzoic acid.—(*Zeitschr. Chem.* N. F. iii. 322.)

Phosphorous Acid, Action of Bromine and Iodine on.—G. Gustavson. Equal molecules of bromine and phosphorous acid act upon each other in sealed tubes at 100° and below, according to the following equation:

$$PH_3\Theta_3+Br_2=2HBr+\underbrace{BH\Theta_3}_{\text{Metaphosphoric acid.}}$$

Four molecules of acid and three of bromine decompose in the following manner—

$$4PH_3\Theta_3+3Br_2=3PH_3\Theta_4+3HBr+PBr_3$$

Iodine combines less readily with phosphorous acid; the reaction between eight molecules of the latter and five of iodine takes place as follows:—

$$8PH_3\Theta_3+5I=6PH_3\Theta 4+2HI+PH_4I+PI_2$$

—(*Akad. Petersb.* xi. 299.)

Thallium.—Wöhler separates this metal from flue-dust in the following manner:—The material is repeatedly extracted with boiling water, slightly acidulated with sulphuric acid, and the filtrate, without previous concentration, precipitated with chlorhydric acid. The chloride is converted into sulphate, and the latter in aqueous solution reduced by zinc or by an electric current derived from a single cell: the metal is finally fused under a layer of potassic cyanide.*—(*Ann. Chem. Pharm.* cxlii. 263.)

Phosphorus, Combinations of.—H. Wichelhaus. The compound $PCl_2(\Theta Br)$ has been obtained (*Menschutkin Ann. Ch. Ph.* 139, 343), by acting upon absolute alcohol with phosphoric terchloride, and substituting in the compound $PCl_2(\Theta Ꞓ_2H_5)$ thus formed, bromine for ethyle. The author has by means of this reaction, but employing chlorine instead of bromine, prepared the compound $PCl_2(\Theta Cl)$, which, he finds, is identical with the ordinary phosphoric oxychloride. This synthesis has some not unimportant consequences. It will be possible, starting from oxychloride or ethylephosphorous chloride, to prepare the compound $P\Theta(Ꞓ_2H_5)_3$ which, supposing it to be identical with the oxide of triethylephosphine, will thus prove the constitution of the latter to be analogous to phosphoric oxychloride—

$$\overset{'''}{P}\left\{\begin{array}{l}\Theta Cl\\ Cl\\ Cl\end{array}\right. \text{ and } \overset{'''}{P}\left\{\begin{array}{l}\Theta Ꞓ_2H_5\\ Ꞓ_2H_5\\ Ꞓ_2H_5\end{array}\right.$$

Further, the constitution of phosphoric acid will be

$$P\left\{\begin{array}{l}\Theta\Theta H\\ \Theta H\\ \Theta H\end{array}\right.$$

showing it to be the mono-oxy-acid of phosphorous acid, and the existence of di- and tri-oxy-acids consequently may be predicted. The other believes to have already obtained the compound

$$\overset{'''}{P}\left\{\begin{array}{l}\Theta\cdot\Theta H\\ \Theta\cdot\Theta H\\ \Theta\cdot\Theta H\end{array}\right.$$

(*Zeitschr. Chem.* N. F. iii. 321.)

Neurin.—A. Baeyer. The constitution of neurin is that of the hydrate of trimethyle-oxethyle-ammonium

$$=N(ꞒH_3)_3\left\{\begin{array}{r}(Ꞓ_2H_4(H\Theta)\\ H\end{array}\right\}\Big\}\Theta$$

The auro-chloride of this base

$$=NꞒ_5H_{14}\Theta Cl,AuCl_3$$

is soluble in hot water, and crystallises in beautiful yellow needles. The hydriodate of neurin has the formula

$$N(ꞒH_3)_3(Ꞓ_2H_4(\Theta H))I.$$

but if neurin is heated with an excess of hydriodic acid, water is eliminated, and the iodide $N(ꞒH_3)_3(Ꞓ_2H_4I)$ I formed, which on being treated with argentic oxide yields a base, the auro-chloride of which has the composition $NꞒ_5H_{12}Cl,AuCl_3$, showing thus a conversion of neurin into a vinyle-compound. The platino-chloride contains one molecule of water. In order to remove any doubt as to the existence of oxethyle $=Ꞓ_2H_4(\Theta H)$ in neurin, the action of acetylic chloride upon the latter had been tried, and a body obtained of the composition

$$\left.\begin{array}{r}N(ꞒH_3)_3(Ꞓ_2H_4)(\Theta,Ꞓ_2H_3\Theta)\\ H\end{array}\right\}\Theta$$

which is neurin wherein an atom of hydrogen is replaced by acetyle.—(*Ann. Chem. Pharm.* cxlii. 322.)

Oenanthylidene and Caprylidene.—E. Rubieu. Oenanthylidene, $Ꞓ_7H_{12}$, is prepared by heating oenanthylenic chloride with twice its volume of a strong alcoholic solution of potassic hydrate, first under ordinary pressure, and afterwards in sealed tubes to 150°, repeating the treatment again and again, until the greater part of the oil, which which separates on addition of water, distils below 120°. From this portion the pure oenanthylidene is obtained after

---

* This is identical with the process by which I prepared considerable quantities of thallium four years ago. For full details see Chemical News, vol. viii., p. 159.—W. C.

repeated fractional distillations, boiling at 106°—108°. It is a colorless, thin liquid, lighter than water, rapidly volatilising at ordinary temperature, burning with a luminous flame, and dissolving in ether, alcohol and benzol. Bromine gives rise to two substitution-compounds—$C_7H_{12}Br_2$ and $C_7H_{10}Br_4$, the latter only having been obtained pure. Caprylidene, C_8H_{14} is obtained from caprylenic bromide by the same process, the reaction taking place somewhat more readily. Bromine produces the compound $C_8H_{14}Br_4$, which on being treated with alcoholic potassic hydrate is converted into $C_8H_{11}Br$.—(*Ann. Chem. Pharm.* cxlii. 294.)

Trichlordracylic acid.—P. Janasch. A boiling mixture of potassic bichromate and diluted sulphuric acid (1 acid to 1 water) converts the solid trichlortoluol (fusing at 75°—76°) into trichlordracylic acid, $C_7H_3Cl_3\Theta_2$. The acid melts at 160°, is readily soluble in alcohol and ether, sparingly so in hot, almost insoluble in cold water. The baric salt crystallises in long needles, and has the composition $C_7H_4Cl_3\Theta_2)_2Ba''$.—(*Ann. Chem. Pharm.* cxlii. 301.)

Trixylylamine.—P. Janasch. This body is formed when chlorxylol (boiling at 200°) is heated with alcoholic ammonia in sealed tubes to 100°. For its separation, the alcohol has to be boiled off, and ammonic chloride removed by washing with water; the remaining oil is then treated with chlorhydric acid, and extracted with ether, the latter dissolving an oily body of, as yet, unknown nature. Trixylylaminic chlorhydrate is insoluble in ether or water, but soluble in alcohol, fuses at 203°—204°, and has the formula $(C_8H_9)_3N,HCl$. Sodic hydrate precipitates the free base, trixylylamine, as a thick oil, heavier than water, not solidifying at −15°.—(*Ann. Chem. Pharm.* cxlii. 303.)

Methylsalicylic acid, formation of.—C. Graebe. The similarity in the behaviour of the hydroxyl-group in phenol and in gaultheria-oil led to the belief that analogous to the synthesis of salicyclic acid (Kolbe and Lautemann) oxyphtalic acid might be obtained by acting upon gaultheria-oil, with sodium and carbonic anhydride, the reaction might be expected to proceed according to the equation:

$$C_6H_4\left\{\begin{matrix}\Theta H\\ C\Theta_2CH_3\end{matrix}\right. + C\Theta_2 = C_6H_3\left\{\begin{matrix}\Theta H\\ C\Theta_2H\\ C\Theta_2CH_3\end{matrix}\right.$$

No acid of the composition of oxyphtalic acid, however, was formed, but salicylic and methylsalicylic acid instead. As carbonic anhydride does not take any part in the reaction, the effect of sodium alone on methylic salicylate had been tried, and it was found that at ordinary temperature the methylic ether of sodiosalicylic acid

$$=C_6H_4\left\{\begin{matrix}\Theta Na\\ C\Theta_2CH_3,\end{matrix}\right.$$

and at 200°—220° sodic methylsalicylate

$$=C_6H_4\left\{\begin{matrix}\Theta CH_3\\ C\Theta_2Na\end{matrix}\right.$$

besides a small quantity of methylic methylsalicylate and sodic salicylate is formed.—(*Ann. Chem. Pharm.* cxliii. 327.)

Hydrophtalic Acid.—C. Graebe and O. Born. Benzol, although a saturated compound, is capable of uniting with two, four, or six monovalent elements, or groups of elements, thus forming the so-called products of addition of the aromatic series which possess the common property of being more or less easily reconverted into compounds of the benzol type. None of these bodies, however, with the exception of quinic acid (*Ann. Chem. Pharm.* cxxviii., 197), have been sufficiently studied to afford a clear insight into their constitution. The present contribution contains the results of the author's researches on the addition of hydrogen to phtalic acid.

Hydrophtalic acid is prepared by adding sodium-amalgam to a solution of 1 part of phtalic acid, 1 of crystallised sodic carbonate, and 8 of water; the acid is then precipitated with chlorhydric acid, recrystallised and decolorised by means of animal charcoal. It is sparingly soluble in cold water and ether, more readily in alcohol and hot water; it may be heated to 200 without decomposition; being a bibasic acid, it forms neutral and acid salts, several of which are described. The decomposition which hydrophtalic acid undergoes with various reagents are shown in the following equations:—With soda-lime:

$$C_6H_6(C\Theta_2H)_2 = \underset{\text{Benzol.}}{C_6H_6} + H_2 + 2C\Theta_2$$

with phosphoric pentachloride:

$$C_6H_6(C\Theta_2H)_2 + 2PCl_5 =$$
$$= \underset{\text{Benzoylic chloride.}}{C_6H_5(C\Theta Cl)} + C\Theta + 3HCl + 2P\Theta Cl_3$$

with sulphuric acid:

$$C_6H_6(C\Theta_2H)_2 + H_2S\Theta_4 = \underset{\text{Phtalic acid.}}{C_6H_4(C\Theta_2H)_2} + 2H_2\Theta + S\Theta_2$$

$$\text{and } C_6H_6(C\Theta_2H)_2 = \underset{\text{Benzoic acid.}}{C_6H_5(C\Theta_2H)} + C\Theta + H_2\Theta$$

with bromine:

$$C_6H_6(C\Theta_2H)_2 + Br_2 = C_6H_5(C\Theta_2H) + 2BrH + C\Theta_2$$

with fusing potassic hydrate:

$$C_6H_6(C\Theta_2H)_2 = C_6H_5(C\Theta_2H) + C\Theta_2 + 2H$$

with nitric acid, or potassic bichromate and sulphuric acids benzoic acid is principally formed. Heated by itself to above 200° hydrophtalic anhydride is obtained. Chlorhydric acid acting upon an alcoholic solution of hydrophtalic acid does not produce the ether of the latter, but benzoic ethide.—(*Ann. Chem. Pharm.* cxlii. 330).

Thallic Acid.—According to E. Carstanjen, thallic acid is formed when a current of chlorine passes through a hot solution of potassic hydrate containing thallic oxide in suspension, the liquid at the same time assuming a crimson colour. The solution may be evaporated and even filtered through paper, without undergoing decomposition; acids decompose the new compound, setting free oxygen. Further details are promised. —(*Journ. Prakt. Chem.* ci. 55).

Molybdates.—F. Ulik finds that there are six series of molybdates, corresponding to the general formulæ:—

1. MO,MoO_3+nHO
2. $MO,2MoO_3$
3. $3MO,7MoO_3+nHO$
4. $MO,3MoO_3+nHO$
5. $MO,4MoO_3+nHO$
6. $MO,8MoO_3+nHO$

Those hitherto known belong to series 1, 3, and 4. The salts of the 4th and 5th series appear in two modifications, a crystalline and an amorphous.

It is further shown that a decided analogy exists between molybdic, chromic, and sulphuric acid, the first forming a magnesic salt analogous in composition to the corresponding sulphate; and in the double salt $KO,MgO,2MoO_3$, one half of the molybdic acid may be replaced by chromic acid.—(*Journ. Prakt. Chem.* ci. 61).

Methoxybenzoic Acid.—C. Graebe and O. Schultzen. It has been shown (*Ann. Chem. Pharm.* cxxxix. 134) that the body obtained by acting upon gautheria-oil with potassic hydrate is potasso-salicylic methide, and that the latter may be converted into methylesalicylic acid; it has likewise been proved that paraoxybenzoic acid, by the same reaction, gives rise to the formation of sodioparoxybenzoic ethide and anisic acid. The object of the present communication is to show that oxybenzoic acid, as regards the derivatives mentioned, behaves like its two isomers.

Oxybenzoic acid, prepared with unimportant modifications according to Fischer's method (*Ann. Chem. Pharm.* cxxxvii. 137), is heated together with potassic hydrate and methylic iodide in sealed tubes, to 140°, when the following reaction takes place:—

$$C_6H_4\left\{\begin{matrix}\Theta H\\ C\Theta_2H\end{matrix}\right. + 2CH_3I + 2KH\Theta =$$
$$= C_6H_4\left\{\begin{matrix}\Theta CH_3\\ C\Theta_2CH_3\end{matrix}\right. + 2KI + 2H_2\Theta$$

The methoxybenzoic methide thus formed is treated with potassic hydrate, and thereby converted into methoxybenzoic acid.

$$=C_6H_4\left\{\begin{matrix}\Theta CH_3\\ C\Theta_2H\end{matrix}\right.$$

The acid is readily soluble in hot water, from which it crystallises in long white needles; it is also soluble in alcohol and ether; it fuses at 95°, and sublimes without decomposition. The argentic salt $=C_8H_7Ag\Theta_2$ is obtained as a white precipitate, soluble in hot water.—(*Ann. Chem. Pharm.* cxlii. 350.)

New Series of Sulpho-compounds.—A. Saytzeff.—Sulphamylic oxide, $(C_5H_{11})_2S\Theta$, fuses at 37—38°. Zincic ethide, ethylic, or amylic iodide are without action upon it; when heated with hydriodic acid in sealed tubes to 100° a brown oil, insoluble in water, is formed. The acid liquor remaining, after sulphamylic oxide has been separated, contains a small quantity of amylsulphurous acid.

Butylic sulphide, $(C_4H_9)_2S$, is formed by heating butylic chloride with an alcoholic solution of potassic sulphide; it separates from the mixture on addition of water as an oily liquid which, after having been dried and rectified, boils between 176 and 185°; it is insoluble in water, soluble in alcohol and ether. Amylethylic sulphide

$$\left.\begin{matrix}C_5H_{11}\\ C_2H_5\end{matrix}\right\}S$$

is obtained by treating sodic amyl-mercaptide.

$$C_5H_{11}NaS$$

with ethylic iodide as a transparent liquid, insoluble in water, and boiling at 158—159°. Treated with fuming nitric acid, the oxide

$$\left.\begin{matrix}C_5H_{11}\\ C_2H_5\end{matrix}\right\}S\Theta$$

is formed, besides a trace of an acid, containing sulphur. These observations differ from those of Carius, who gives the boiling point of the sulphide at 132—133·5°, and who has obtained ethylsulphurous acid as the only product resulting from the action of nitric acid.

Sulphethylic oxide $(C_2H_5)_2S\Theta$, is obtained by the action of nitric acid on ethylic sulphide; it is a thick, nearly colourless liquid, which crystallises on cooling. Reducing agents reconvert it again into ethylic sulphide; further oxidation produces diethylsulphan.

Sulphomethylic oxide $(CH_3)_2S\Theta$, is prepared, like the ethyle-compound, by acting upon methylic sulphide with strong nitric acid; the same reaction gives rise to the formation of nitrate of sulphomethylic oxide

$$(CH_3)_2S\Theta.HN\Theta_3$$

which is a crystallisable, deliquescent salt. If a solution of the methylic sulphide in nitric acid is heated for several hours in a sealed tube methylsulphan is formed, which is soluble in water, fuses at 109° and boils at 238°. The action of methylic iodide on amylethylic sulphide was expected to result in the formation of the compound $S(CH_3.C_2H_5.C_5H_{11})I$: instead of this, however, iodide of trimethylsulphin $S(CH_3)_3I$ was formed, besides ethylic and amylic iodide.—(*Zeitschr. Chem.* N. F. iii. 358.)

Sodic Hydrate, Crystallised.—E. Schöne. A hot saturated solution of sodic hydrate begins to crystallise when cooled to between 40 and 50°. The crystals have the composition $Na_2\Theta+5H_2\Theta$ or $Na_2H_2\Theta_2+4H_2\Theta$. They are very deliquescent, but after being thoroughly dried upon a porous surface under the desiccator, do not fuse below 80°.—(*Zeitschr. Chem.* N. F. iii. 383.)

Thionessal.—M. Fleischer. The formula of thionessal according to the author is $C_{28}H_{20}S$, instead of $C_{26}H_{18}S$ as stated by Laurent and Märker. Bromine substitutes three atoms of hydrogen forming $C_{28}H_{17}Br_3S$ which may be obtained in crystals from its solution in petroleum (of a high boiling point) fusing at 265°—267°. This compound again treated with bromine is converted into $C_{28}H_{16}Br_4S$. Potassic chlorate and chlorhydric acid oxidise all the sulphur of thionessal into sulphuric acid, converting it thereby into the compound $C_{14}H_{10}\Theta$, which fuses at 214°. Phosphoric chloride forms C_7H_5Cl (or χC_7H_5Cl), fusing at about 130°. Fuming nitric acid first produces the nitro-compound $C_{28}H_{16}(N\Theta_2)4S$ which subsequently is converted into a body, free from sulphur, probably $C_{14}H_{10}(N\Theta_2)_2\Theta_3$, and finally into nitrodracylic acid. Fuming sulphuric acid dissolves thionessal with disengagement of sulphurous acid, and formation of the acid $C_7H_6S\Theta_4$, the baric salt of which has the composition $(C_7H_5S\Theta_4)_2Ba4H_2\Theta$. The compound produced by the action of soda-lime seems to be tolallylic sulphide $C_{14}H_{10}S$.—(*Zeitschr. Chem.* N. F. iii. 376.)

Mercuric Naphtide.—R. Otto. Sodium-amalgam was made to act upon monobromnaphthalene, diluted with several times its volume of benzol (boiling between 120 and 140°) in the hope of getting dynaphtyl

$$\left.\begin{matrix}C_{10}H_7\\ C_{10}H_7\end{matrix}\right\}$$

The reaction, however. proceeded differently—mercuric naphtide being formed according to the equation:—

$$2\left.\begin{matrix}C_{10}H_7\\ Br\end{matrix}\right\} + Na_2Hg''=\left.\begin{matrix}C_{10}H_7\\ C_{10}H_7\end{matrix}\right\}Hg'' + 2NaBr$$

Mercuric naphtide, which may thus be prepared with ease, and in any quantity, crystallises in white needles, soluble in hot benzol, sparingly so in alcohol, insoluble in water; they fuse at 248°.

When heated with lime naphtalene principally is formed, but no dinaphtyl. Iodine combines with mercuric naphtide, forming mercuric di-iodmercaptide,

$$\left.\begin{matrix}C_{10}H_7\\ C_{10}H_7\end{matrix}\right\}HgI_2$$

which crystallises from hot alcohol in beautiful silky needles. Bromine added in excess acts in the following manner:—

$$\left.\begin{matrix}C_{10}H_7\\ C_{10}H_7\end{matrix}\right\}Hg+4Br=2\left.\begin{matrix}C_{10}H_7\\ Br\end{matrix}\right\}+HgBr_2$$

Naphtalenic bromide.

By the action of sodium-amalgam sulphonaphtalenic chloride is resolved into naphtalene and sulphurous acid:—

$$\left.\begin{matrix}C_{10}H_7S\Theta_2\\ Cl\end{matrix}\right\}+2H=S\Theta_2+HCl+C_{10}H_8$$

(*Zeitschr Chem.* N. F. iii. 377.)

Isomer of Ethylamyle, and Observations on Mixed Ether.—Reboul and Truchot. When hexylic chloride is acted upon by alcoholic potassic hydrate, hexylene C_6H_{12} is formed, (Pelouze, Cahours), but besides this ethylhexyl; heptylic, octalyc, and decylic, chloride likewise are converted into both the hydrocarbon and mixed ether; amylic chloride gives chiefly ethyl-amyle, but also some amylene, even ethylic bromide yields besides ethylic ethide, ethylene. This reaction, therefore, is a general one, the members of the series differing in this respect, that the lower ones give rise to the formation of mixed ether principally, while those of higher atomic weight yield hydrocarbon more abundantly. By the action of alcoholic potassic hydrate upon amylenic bromhydrate a body is obtained of the composition of ethyl-amyle, but differing from the latter in boiling-point by about 10°, as also in its behaviour towards hydrobromic acid,—ethyl-amyle forming ethylic and amylic bromide, the isomer ethylic bromide and amylenic bromhydrate. The authors propose for the isomeric compound the formula:—

$$C_5H_{10}\left\{\begin{matrix}H\\ C_2H_5\Theta\end{matrix}\right.$$

(*Comptes R.* lxiv. 1243.)

MISCELLANEOUS.

Intercolonial Exhibition, 1866-7.—The shadow of the Paris Exhibition has, it is true, obscured somewhat the *éclat* of the similar event of the Southern World, but the history of the latter is well worthy of a short record. A few months ago, the Governor of Victoria publicly received the report of the jurors, and formally declared their awards at Melbourne. Up to the middle of February the number of admissions had been 242,892, which speaks well for the interest taken by the inhabitants of a thinly inhabited district in their national undertaking. A few notices of these awards will give a very fair notion of the character of this Exhibition, and will serve as a basis for comparison between it and similar European festivals. The public spirit shown in the Southern hemisphere cannot be mistaken, for it is most probable that this national work will remain as a permanent exhibition, while in England at the present time no decided step has been taken to secure any of the marvels of the Paris Exhibition for the public, the more valuable of which have already been bespoken by foreign governments. The most interesting department of course is that of the ores and non-metallic products, in which medals are allotted for nuggets, ingots, and granulated samples of gold and silver auriferous quartz and colonial gems. Antimony was exhibited in abundance, and native copper of a very superior character. Mr. G. Milner Stephens, F.R.S., received a medal for gems and precious stones; tin-ore, slate, and limestone, were exhibited, but by far the greatest interest is attached to the coal from Newcastle (neither upon Tyne, nor under Lyne), the shale from the Hartley Kerosene Oil and Paraffin Company, and the kerosene from the Western Kerosene Oil Company. Similar shales were sent from New South Wales and Tasmania, also coals from both; from the latter country also the most valuable topazes were sent. South Australia carries off the palm for the following valuable minerals: copper ores, bismuth, plumbago, cobalt and its ores. The ores from Western Australia, for which medals are awarded, were copper only. New Zealand produces, in common with the other colonies, gold and coals, with plumbago and *Titaniferous iron ore*, with novelties in the way of chromium ores and alum. The absence of all mention of platinum would lead us to the conclusion that it is almost the only metal of commercial importance not found plentifully in Australia. The chemical products, when contrasted with the brilliancy of the preceding, are rather meagre, the leading items for which medals are awarded, being "a beautiful sample of higher tarascaci," colonial soft soap, and fluid magnesia. Several awards were made for photographic chemicals, one for commercial mineral acids from Victoria, two for colonial made ink, these with Moulder's coal-dust colonial made ink, and fine quality blackings, exhaust the products for which awards were made in this section of "Chemical and Metallurgical Products and Processes." In the section for horns, hoofs, bones, etc., we notice stearine candles, silicated soaps, anti-corrosive composition for ships' bottoms, superphosphate of lime, deodorising powder, Victorian guanos. The native oils and waxes possess a special interest, with sperm oil, black whale oil, spermaceti, etc. In another department many medals were given for preserved meats, and essence of beef, chiefly from New South Wales. Of general interest will be the awards of medals to Mr. Allport for salmon two years old, smolt and perch, to the Acclimatization Society for the Angola goats, alpacas, and llamas: we mention these especially to show the spirit that exists in the colony. The following are prepared in Australia now also—formerly imported from foreign countries—arrow-root, coffee, and spices in great abundance, starch, maizena, granulated potatoes, "a very valuable article for long voyages;" maccaroni and vermicelli are also commended as a good specimen of a new industry. The Netherlands India Society received medals for tea, coffee, nutmegs, and cloves. New Caledonia is very ably represented, thanks to the exertions of the eminent scientific workers, who have prepared specimens of gluten, starch, and sugar, from the various native plants of that colony. A separate class is formed for chemical and philosophical apparatus. We might prolong this notice to an indefinite length, but will allude only to the sections for native wines and liqueurs, glass manufacture, and photography, with photographs of the Aborigines. In conclusion, we may add that the interest taken by neighbouring States in it, has given to this Melbourne Exhibition quite an international character; every one of our Australian colonies exhibited, and products were also sent from the Mauritius and the French settlement of New Caledonia. The Australian Maraschino, brandy, Hermitage, and Burgundy, may perhaps attract attention even at Paris, where one of the best conducted English departments is imported directly from Melbourne; we allude to that of Messrs. Spiers and Pond, who, as recognized representatives of England at Paris, bear witness to the rapid strides in civilisation made by our Australian colonies.

"Artificial Gold."—The following alloy, "artificial gold," as it is called, has been lately the subject of correspondence in the *Mining Journal*, etc., and is hailed as a grand discovery likely to serve the Cornish copper and tin mines, by introducing a new demand for these metals. The description here quoted is from the *Engineer*, of July 19, 1867, as follows:—"It is stated that an American has discovered a beautiful alloy, which has been most successfully applied as a substitute for gold; it is composed of pure copper, 100 parts; pure tin, 17 parts; magnesia, 6 parts; tartar of commerce, 9 parts; sal ammoniac, 3·6 parts; and quicklime, 1·6 part. The copper is first melted then the lime, magnesia, sal ammoniac, and tartar are added, little at a time, and the whole is briskly stirred for about half-an-hour, so as to mix thoroughly, after which the tin is thrown on the surface in small grains, stirring until entirely fused. The crucible is now covered, and the fusion kept up for about thirty-five minutes, when the dross is skimmed off, and the alloy found ready for use. It is quite malleable and ductile, and may be drawn, stamped, chased, beaten into powder, or into leaves, like gold-leaf. In all of which conditions it is not distinguishable from gold even by good judges, except by its inferior weight. The alloy has already been largely applied in the United States, and requires only to be known in Great Britain to become a favorite."

The Metric System.—Interpretation of the Act of 1864.—During the past year a subject of some importance, involving the legal construction of the Metric Act of 1864, was brought to the notice of the Board of Trade. One of the inspectors of weights and measures for the county of Surrey stated that he had seized some metric weights in a tradesman's shop in Southwark, as being illegal. On his bringing the matter before the magistrates at the Newington Sessions House, the defendants alleged that the Metric Weights and Measures Act, 1864, 27 & 28 Vict. c. 117, permitted the use of metric weights, but gave the inspector no power to examine them. The magistrates dismissed the information, observing that the Act was loosely drawn, and they advised the inspector not to seize metric weights, as the defendants were justified under the Act in using them. Upon this subject the Board of Trade directed a case to be prepared for the opinion of the law officers, who gave their opinion that, notwithstanding the provisions of the Metric Act, a person *using* material metric weights and measures is liable to have them seized, and to conviction and forfeiture of the weights, under the Act 5 & 6 Will. iv. c. 63.

Pharmaceutists and the Jury Lists.—We have been requested to remind members of the Pharmaceutical Society, and others who may be entitled to claim exemption from serving on juries, that the churchwardens and overseers receive, during the month of July, the precept to return lists of persons qualified to serve on juries for the ensuing year; and that in August such lists are prepared and affixed to the church doors, etc. Pharmaceutical chemists should see that their names are not inserted in such lists, and, if inserted, should attend on the day of appeal and present their legal certificate of registration and exemption; such certificate may be obtained from the registrar of the Pharmaceutical Society, 17, Bloomsbury Square, on payment of 1s.

Quekett Microscopical Club.—The second annual general meeting was held in the library of university college on Friday the 26th ult. Mr. Ernest Hart, President, in the chair. The report of the committee showed that the society now numbers 273 members, of whom 130 were elected during the year; that many papers of microscopic interest had been read, field excursions successfully carried out, and class instruction in the uses of the microscope afforded to the younger members. The treasurer's report gave a satisfactory balance and in every way the club was in a very prosperous state. The president delivered an address, in the course of which he congratulated the members on the remarkable success which had attended the operations of the year, and on papers having been read which would bear comparison with those of any other club. He urged the members to remember that the microscope was not only a source of amusement but an instrument of research, and it was its real use which ought rather to be cultivated. Amusement and research were not incompatible, and the contemplation of minute forms was in itself a means of recreation, but the true microscopist is he who looks through form and structure to discover uses and laws, who is never contented with endeavouring to ascertain what are its relations, merely with a view to systematizing, but as a means to an end. Whether we consider the study of the microscope as an intellectual amusement or look into it as teaching some of the very highest truths relating to law, order and power in the universe, we yield only to the convictions which are taught us whilst looking upon structure in relation to the causes which modify it. The following officers were elected for the ensuing year:—President, Mr. Arthur E. Dunham, F.L.S. Vice-Presidents — Dr. Tilbury Fox, M.R.C.P.; Mr. Ernest Hart; Mr. William Hislop, F.R.A.S.; Mr. John K. Lord, F.Z.S.; Treasurer — Mr. Robert Hardwicke, F.L.S.;—Hon. Secretary—Mr. Witham M. Bywater;—Hon. Secretary for foreign correspondence — Mr. M. C. Cooke;—Committee—Mr. W. J. Arnold, Mr. N. Burgess, M. S. J. McIntire, Mr. J. Slade.

Petroleum as Fuel.—According to Adam's trials with petroleum for heating boilers, the following advantages, in comparison to coal, resulted:—Quicker steam generation, smaller dimensions of fire-place and boiler, constant firing, no smoke, ashes, or residua (these amount from 7 to 16 per cent. when using coal); possibility of having an intense fire at once without the assistance of increased draught (this is of great importance to steam vessels); easier working, and considerably smaller store-rooms than coal would require.—*Revue Univers* X. ann., livr., p. 206, with drawing.

Fusibility of Aluminates containing a large amount of lime.—(Fremy.) Mixtures of 80 parts lime and 20 alumina and 90 parts lime and 10 alumina become liquified when heated in crucibles in a wind furnace. Mixtures of 93 lime and 3 alumina still frit at such temperature. The cooled masses have crystalline fracture, alkaline reaction, swell up in water, and may be used in metallurgy on account of their affinity for sulphuric and phosphoric acid.—(*Dingl. P. bd.* 177, p. 376.)

A New Science Scholarship.—On Friday, 26th ult., was celebrated the 30th anniversary of the City of London School, and upon that occasion a report was presented detailing the progress made towards the foundation of a *Testimonial Scholarship* in honour of the Rev. G. W. F. Mortimer, D.D., late head master, whose eminent services in the cause of education, and especially in the successful conduct of the school for a period of more than a quarter of a century, were deemed worthy of public and permanent recognition. For the purpose of giving effect to this resolution a committee, composed of old pupils of the school, and a few leading members of the Corporation, took the matter in hand shortly after Dr. Mortimer's retirement, and invited subscriptions, which already amount to about five hundred pounds. This sum will, it is believed, be further augmented, so that an annual grant of at least twenty pounds may be realised. It has now been proposed by Mr. Ernest Hart, one of the secretaries, to devote the proceeds to the encouragement of the study of science in the school, and, by granting an annual premium, assist in supporting a pupil either at the Royal College of Chemistry, or other scientific educational establishment of Great Britain. This proposal met the hearty approval of the subscribers, and its expediency was strongly urged by Mr. Thomas Hall, B.A., who for twenty years past has conducted the science classes in the City of London School. When this suggestion has been finally decided upon we will inform our readers; in the meanwhile, it should be mentioned that there is already a medical scholarship (tenable for three years at St. Thomas's Hospital), and that Mr. Alderman Hale presents a silver medal for proficiency in chemical science, to be competed for annually by the pupils, all of whom, to the number of six hundred, are now taught chemistry as a branch of general education in the school. We notice the names of Mr. W. H. Perkin and Mr. J. Spiller among those acting on the committee, and in the list of subscribers to the Testimonial Fund are to be seen the names of several other chemists who received their early scientific training in the school. The treasurer, J. Sharp, Esq., LL.D., was also formerly one of Dr. Mortimer's pupils.

Composition and Quality of the Metropolitan Waters in July, 1867.—The following are the Returns of the Metropolitan Association of Medical Officers of Health:—

Names of Water Companies.	Total solid matter per Gallon.	Loss by ignition.*	Oxydisable organic matter.†	Hardness.	
				Before boiling.	After boiling.
Thames Water Cos.	Grains.	Grains.	Grains.	Degs.	Degs.
Grand Junction.	18·67	0·75	0·82	1·25	4·0
West Middlesex.	17·44	0·60	0·71	12·5	3·5
Southwark and Vauxhall.	18·16	0·42	0·71	12·5	4·0
Chelsea.	17·80	0·59	0·71	13·0	4·0
Lambeth.	17·51	0·72	0·80	12·5	3·5
Other Companies.					
Kent	28·49	0·50	0·42	15·5	7·5
New River	17·00	0·49	0·39	12·5	5·0
East London	17·83	0·49	0·46	12·5	5·0

* The loss by ignition represents a variety of volatile matters, as well as organic matters, as ammoniacal salts, moisture, and the volatile constituents of nitrates and nitrites.

† The oxydisable organic matter is determined by a standard solution of permanganate of potash—the available oxygen of which is to the organic matter as 1 is to 8; and the results are controlled by the examination of the colour of the water when seen through a glass tube two feet in length and two inches in diameter.

The amount of ammonia in the water and of that derivable from organic nitrogen did not in any case exceed the 0·0094 of a grain per gallon of water, and there was no organic nitrogen or ammonia in the Kent water. It was, therefore, absolutely free from organic matter of an animal origin.

H. Letheby, M.B.

The State of the Thames.—In a letter to the *Times* dated Aug. 7th, "Y" writes, that last night during low water the characteristic stench of the Thames was distinctly perceived by several independent observers on the terrace at the Houses of Parliament, though in a less degree than in former times. As the water of the river is chemically examined from time to time by persons appointed by the Board of Health, it would be interesting to learn from them whether either the proportion or condition of the organic matter in the water will explain the unwelcome fact.

Economy of Light in Dark Alleys.—If in a very narrow street or lane we look out of a window with the eye in the same plane as the outer face of the wall in which the window is placed, we shall see the whole of the sky by which the apartment can be illuminated. If we now withdraw the eye inwards, we shall gradually lose sight of the sky till it wholly disappears, which may take place when the eye is only *six* or *eight* inches from its first position. In such a case the apartment is illuminated only by the light reflected from the opposite wall, or the sides of the stones which form the window; because, if the glass of the window is *six* or *eight* inches within the wall, as it generally is, not a ray of light can fall upon it. If we now remove our window and substitute another in which all the panes of glass are roughly ground on the outside, and flush with the outer wall, the light from the whole of the visible sky and from the remotest parts of the opposite wall will be introduced into the apartment, reflected from the innumerable faces or facets which the rough grinding of the glass has produced. The whole window will appear as if the sky were beyond it, and from every point of this luminous surface light will radiate into all parts of the room. In order to explain the superior effect of roughly ground glass, let us suppose that the ordinary window is replaced with a single sheet of the best glass inserted flush with the outer wall. The whole of the light from the visible portions of the sky will fall upon its surface, but at such an obliquity that four or five-sixths of it will be reflected outwards, and the other two or one-sixth, which is transmitted, will fall on the floor or on the shutters, and be of no value.—*Sir D. Brewster.*

The Earliest Universal Exposition of which we have any record, was held at Rome in the days of Nero. The philosopher and moralist, Seneca, gives the following account of it: "I was present, the other day, at a solemn exhibition of the wealth of Rome; where I saw statues which were marvels, perfect masterpieces; exquisite stuffs and draperies, and costumes brought from countries even beyond the Roman frontiers," etc.

Nitro-Glycerine in Blasting.—A correspondent of the Nevada *Gazette*, who has recently visited the summit tunnel on the Central Pacific Railroad, writes that the contractor thinks they are going ahead with the tunnel fully twenty-five per cent. faster by the use of nitro-glycerine than they could by using powder. The small holes required for the oil can probably be drilled in less than one-third the time required far larger ones necessary in using powder. The oil does much more execution than powder, as it always breaks the rock from two to sixteen inches beyond the hole, and also throws out a much larger body. The oil in hard rock shows a strength five times greater than powder, pound for pound. It is made upon the spot, and is considered much stronger, as well as safer, than that imported. They have now been using it for several months, and have never yet had a premature explosion, or any other accident, and not a single blast has missed fire since the Chinamen commenced filling the cartridges. The work upon this road seems to have fully set at rest the superiority of nytro-glycerine over powder, both for economy and safety. Of course this applies to the oil made upon the spot, and not to the imported article.

Clarifying Action of Sulphate of Alumina on Turbid Water.—Whatever be the nature and quantity of the earthy substances held in suspension in turbid water, it becomes fit to drink in from seven to fifteen minutes if to each litre there be added ·04 grammes of finely powdered alum—care being taken to agitate the liquid when the alum is introduced (this is about ¾ lb. per ton of water). If potash alum is used the alum is decomposed into sulphate of potash, which is all dissolved by the water and sulphate of alumina, which, by its decomposition, purifies the water. The alumina separates in an insoluble form, and carries down with it as it precipitates the matters which render the water troubled, and the organic matter. The acid attacks the alkaline and earthy carbonates, and transforms them into sulphates. The water becomes slightly richer in bicarbonates and free carbonic acid, whilst all organic matter is destroyed. Seven parts of sulphate of alumina will purify as much water as ten parts of rock alum or potash alum, and the sulphate of alumina does not introduce any alkaline sulphate into the clarified water.—*Technologiste*, vol. xxiv., p. 197.

What is Fame!—The following extract from an *American* scientific paper somewhat surprises us. The only explanation we can offer is, that the paragraph was possibly translated from the *French.* "Offers of knighthood have been made and refused by several of the distinguished mechanics and men of science in Great Britain, ; James Watt refused knighthood, as did Michael Faraday. The latter commenced life as a poor mechanic, and worked up to the head of his profession; is an honorary member of the Institute of France, Fellow of the Royal Society, an able author on engineering subjects, and is the inventor of the cellular hollow girder system upon which the Britannia tubular bridge is built."

How to Produce Stoneless Fruit.—At a late meeting of the Agricultural Society in India, the Rev. Mr. Firminger communicated a plan by which the stones of fruit may be reduced or made to disappear, and the pulp increased in size and flavour. At any time during the cold season select a branch that is to be used afterwards for inarching. Split it up carefully somewhat less than a span long. From both halves of the branch thus split scoop out cleanly all the pith; then bring the split halves together again, and keep them bandaged till they have become thoroughly united. At the usual time, the beginning of the rains inarch the branch thus treated upon suitable stock, taking for the place of union the portion of the branch just below where the split was made. Upon a branch of the tree thus produced a similar operation is performed, and so on for successive seasons, the result being that the stone of the fruit becomes less and less after each successive operation. This process has been applied likewise to the grape vine at Malaga, and plants thereby have been produced which bear the finest fruit, without the slightest vestige of a stone within them.—*Mining Press.*

Explosion of Gun-cotton.—On Monday afternoon an explosion occurred in a building used for the purpose of drying gun-cotton at the works of Messrs. T. Prentice and Co., Stowmarket. The building was a two-storied one, the bottom being built of clay lumps, and the upper part of wood with a lining, the space being filled up with sawdust packing. The roof was of slate. The building was situated near the bank of the river on the railway side, at the further end of the works. The custom has been to place the manufactured cotton in the building moist, and to subject it for a time to heat varying from 90° to 120°. This heat was imparted by means of pipes from an adjacent shed, in which were a series of stacks of horizontal pipes generating heat from steam conveyed to them by a pipe across the river. About 3 p.m. a loud. dull report was heard, followed by another sharper report, and the building attacked was levelled with the ground, while the ruins were in a blaze. The flames spread to another drying shed, in which was a quantity of the sheets of paper used in cartridges, hung up for drying. The roof of this shed was blown up, and the flames thence extended to some large tanks containing cotton in process of manufacture. Some of the covers were burnt, but the cotton was only blackened in places. Some trees on the railway side of the works were burnt and scorched, and some cattle belonging to Mr. Arnold Scuttle were badly burnt. No person was in the shattered buildings when the explosion took place, although two men named Conham and Broom had been in the drying shed a few seconds before the accident happened. The occurrence is attributed to over heating; the sun made the roof very hot, and the pipes forcing in more hot air, the temperature was raised to 170°, at which gun-cotton explodes.—*The Times.*

[If 170° refers to Fahrenheit's scale it is entirely wrong. Professor Abel places the exploding point of gun-cotton at about 150° C., which is equivalent to 302° F.—Ed. C.N.]

Legalised Poisoning.—It is high time that steps were taken to compel the Metropolitan Railway Company to supply their passengers with air which can be inhaled without danger to life. Travelling daily along that line, we have noticed for some months past that the atmosphere, especially between Baker Street and King's Cross, has been getting more and more foul, until at the present time it is almost unbearable. Sulphurous acid is almost habitually present in such quantities as to render breathing painful, and to induce a feeling of suffocation. That these statements are not exaggerated is proved by the shocking death which actually took place at one of these stations one day last week. The inquest was held by Dr. Lankester. The deceased, Sarah Dobner, whilst at the station, complained of great difficulty of breathing, and said she was in great pain. A medical man advised her removal to the hospital, but it was then believed she was dead. Mr. Anderson, one of the surgeons at St. Mary's Hospital, who made the *post mortem* examination, said the deceased was labouring under disease of the bronchial gland, and undoubtedly the suffocating air of the Underground Railway had accelerated death. The coroner said he had experienced the depressing effect of that railway, and therefore avoided it as much as possible. The tunnels and stations should be ventilated, but he supposed that would not be done until some shocking loss of life from suffocation had occurred. The jury returned a verdict of "Death from natural causes, accelerated by the suffocating atmosphere of the Underground Railway." The Underground Railway is, however, not the only place where a neglect of the most ordinary dictates of common sense has occasioned loss of life. The *British Medical Journal* last week chronicled the poisoning of a young clerk by the bad atmosphere of a small telegraph-office room, ill ventilated, and with four gas-burners, of which "all the clerks had complained." This is only a rapid and compressed view of a tragedy constantly being worked out more slowly in work-rooms and offices, and approximately imitated by the poisoning and illness due to the bad ventilation of our gas-lit theatres, churches, and ball-rooms.

Double Sesquichloride of Iron and Sodium.—I produced this combination, which, as far as I know, is a new one, by the action of hydrochloric acid upon artificial ultramarine. The silicate becomes separated, and if water be added and the solution filtered, the double chloride in question, which is colourless, will be found in the filtrate. The following equation will serve as a further explanation:—

$$\left(\left.\begin{matrix}Na_2\\Al\\Si_2\end{matrix}\right\}O_8+Na_2O+FeS_2\right)+8HCl=$$

$$=\left.\begin{matrix}Na_2\\Al\\Si_2\end{matrix}\right\}O_8+H_2O+3H_2S+\left.\begin{matrix}Na_2\\Fe\end{matrix}\right\}Cl_8$$

By writing upon paper with the solution and afterwards warming it, the letters become black, just as in the case of some sympathetic inks. As the writing does not disappear again by the action of water, it is to be supposed that sesquichloride of iron and sodium is decomposed by heat—*J. Landauer.*

The Standard Pound.—It appears from the reports of the Comptroller-General of the Exchequer that the Exchequer standard avoirdupois pound is actually at the present time in a most unsatisfactory condition, "oxidated on the surface, practically erroneous on the face of it, and known to be erroneous;" and as all the Exchequer standard weights are made of brass, a metal stated to be peculiarly liable to oxidation in the atmosphere of London, and described by Professor Miller as "quite unfit, unless well protected by gilding, to be used in the construction of weights having that degree of accuracy which is required in secondary standard," it is to be feared that others of these Exchequer standard weights may be wanting in accuracy.

Petroleum as Fuel.—The idea of employing petroleum as a substitute for coal in the generation of steam has for some time engaged the attention of scientific men in America, and recently, under the auspices of the Navy Department, a series of experiments on the subject has been carried on at Boston, and there seems a fair prospect that the investigations will result successfully. A gunboat called the Palos was used for the experiments. She had been built for the Government, to make a speed of eight knots an hour, and with coal could never be forced beyond that. First, she was tied to the dock, and the possibility of getting up steam with petroleum was demonstrated. She was then sent on a trial trip down the harbour. Steam was got up with petroleum in 25 minutes, and the Palos steamed down the harbour and back, a distance of 25 nautical miles, in 1 hour and 55 minutes. In making this trip she consumed but four barrels of petroleum! The fires are reported to be kindled and extinguished with nearly the same ease as lighting and extinguishing a gas-burner. The furnaces of the Palos, originally built for burning coal, were fitted at comparatively small expense with burners to which the petroleum was led by pipes from the tanks on deck. The burners, by their own heat, turn the petroleum in the pipes into gas, and in this form it is burnt. The flames produced are intensely hot, and the petroleum burnt on the trip produced as much steam as 20 times its bulk in coals—a great saving of room in ocean voyages. The dangerous properties of the petroleum appear to be the only drawback to its use in this way, for coal-burning furnaces can be adapted to its use at but a trifling expense. The supply of petroleum is now so much greater than the demand that, even with three-fourths of the wells in the producing regions abandoned it can be bought for 2d. a gallon. Its cheapness is therefore another strong inducement to use it for generating steam.

The Queen's English at Paris.—The following is a literal copy of a handbill which has been extensively circulated in the Exhibition by a Spanish firm: "Blacking, ocly and resinous, titled the emperor of the blackings black ink and of allcolours to write with of D. J. G. . . . member of the national academy of Great Britain. This Blackings is knoconed to be the most useful for the conservation of the shes, for its brilliancy, solidity, and complete discomposition of the black animal. Mr. J. G. dus a present of £20 sterling to the person that will present hum a blacking in paste, that will reunite the same conditions, as the Emperor of the Blackings."

Popular Scientific Information.—The following paragraph, from the pages of a weekly contemporary which makes great pretensions to accuracy, shows the kind of science on which the mining public are fed:—"An invention has been provisionally specified by Mr. Bonneville, of Paris, for obtaining white lead direct from the ore, by pouring the molten metal into cold water, to render it as porous and bulky as possible; it is then dissolved in sulphuric acid, and the sulphate is treated with pyroligneous or oxalic acid, combined or not with tincal dissolved in water, and next dried over the fire on ways. The vessels employed are either made of stone or wood, lined with lead, which become coated with a protecting covering of lead."

Red Lead, according to Barton, may be produced by heating oxide of lead to redness with nitrate of soda, or by heating at the same temperature a mixture of 1,894 parts of sulphate of lead, 665 parts of carbonate of soda, and 177 parts of nitrate of soda. The resulting mass is to be washed. —*Berggeist*, No. 50.

Poisoning by Chlorine Vapour.—Professor Maisch says that a direct antidote to the poisonous effects of the inhalation of chlorine is sulphuretted hydrogen, the halogen combining instantly with the hydrogen, liberating sulphur. The professor has tried it himself after accidentally inhaling chlorine, and obtained immediate relief. The same remedy would doubtless be effectual in cases of bromine poisoning.

The Poisonous Action of Phosphorus.—Contrary to the current doctrine that death in case of poisoning by phosphorus results from fatty degeneration of the liver, produced by phosphorous acid, M. Dybkowsky states in a recent memoir that the toxic result is entirely due to the formation of phosphuretted hydrogen gas, which in passing through the blood completely uses up the oxygen present. Hence he concludes that death from phosphorus is nearly equivalent to death by asphyxia.—*Medical Times and Gazette.*

Methylated Spirits.—After the 1st of October next the duty on licenses to retailers of methylated spirits is to be reduced to 10s. per year.

Anti-incrustation Mixture for the prevention of the formation of sediments (strongly adhesive) in steam boilers. 125 kilos. of crystallised chloride of barium dissolved in 50 kilos. of water with addition of 25 kilos. of hydrochloric acid (specific gravity 1·20). To every 1000 litres = 1 cubic mètre = 35·5 cubic feet English, 15 litres of this acid solution should be applied.—*Elsner's Chemisch. Technisch Notizen.* 1867.

Technical Education.—The following extract from *The Times'* account of the "safe contest," forms an appropriate commentary on the remarks on Technichal Education in the supplement to last week's Chemical News (*Amer. Reprint for Oct.*, 1867, p. 175):—"Mr. Herring's workmen were three intelligent Germans—one of them a man of marked ability—he spoke three languages—and went about his business in the most scientific way. Mr. Chatwood's men were three Lancashire men, who represented brute force rather than intellect. One of them had a wonderful touch both for power and precision; but that was the only thing remarkable in the party. Any one who saw the contest between these two sets of workmen would carry away a very vivid idea as to the nature of the race which is now being run between the manufactories of England and those of the Continent. It is an admitted fact that the Continent has made an immense stride in advance, that the progress which we in England have made in the last 15 years is as nothing compared with that which our continental rivals have made, and that it will cost us a good deal in the future not merely to hold our own, but to save ourselves from being disgracefully beaten. The chief reason which the most intelligent observers assign for this change in our position as manufacturers is to be found in the superior education of the continental workman. He has gone through a regular course of instruction at some polytechnic school, he has been trained to appreciate principles, and he brings the exercise of brain to his work. An English foreman is of another stamp. He has had no special education; he has risen from the ranks; he knows his business by rote and rule of thumb; long practice has given him a certain mechanical facility of touch, but science he has none. By the very laws of the trade to which he belongs science is in a manner forbidden to him. Science will teach him to do in an hour what hitherto has occupied him two hours. This science is expressly forbidden him, because it would interfere with the wages of his comrades and take the bread out of their mouths."

Silicates of Methyl.—C. Friedel and J. M. Crafts first tried to prepare this body by reacting on methylic alcohol with chloride of silicium; like Ebelmen, they obtained a product impossible to purify, turning brown in the air and possessing a fœtid odour. They noticed that this product always contained chlorine. Wood spirit was purified by treatment with chloride of calcium; the chloride of calcium compound decomposed with water, and the alcohol rectified several times with sodium. The alcohol thus prepared was sealed in a tube with silicate of ethyl, and the mixture heated during 20 hours at 210° C. After several fractional distillations the principal product isolated from the contents of the tube was a liquid boiling at 143° to 147°. This liquid gave on analysis numbers which correspond with the composition of a mixed silicate, diethylic, dimethylic, silicic ether. There being reason to believe that a minute trace of water contained in the methylic alcohol interfered with the success of the processes in which it was employed, this alcohol was distilled twice with sodium, then with a small quantity of anhydrous phosphoric acid. Thus prepared, it boils at 65·5°, has not the disagreeable odour it usually has, smells like common alcohol, and does not turn brown with soda. Methylic alcohol purified in this way, when added to chloride of silicium, reacts like ordinary alcohol. When the theoretical quantity of the alcohol has been added, the product is distilled, and after a small number of fractional distillations two principal products are obtained, one boiling at 120° to 122°, and the other at 201° to 202·5°. The first is the normal silicate of methyl; the second is the hexamethylic disilicic ether. The normal silicate of methyl is a colourless liquid, has rather an agreeable odour, is soluble in a considerable quantity of water. Moisture or aqueous alcohol gives rise to condensed products, ultimately silica. It burns with a white smoke composed of silica.—*Silliman's Journal*, May, 1867.

Nitroglycerine.—The destruction of the *European* at Colon by an explosion of nitroglycerine, has been the cause of an action at law. The plaintiffs—the West India and Pacific Steamship Company—were the owners of the vessel; the defendants—Guion and another—merchants and forwarding agents. The defendants had received from their correspondents in Hamburg, Messrs. Bandemann, 70 cases of oil, described in the letter of advice as "glonoin oil," and one of 20,000 percussion caps to be forwarded to San Francisco. It appeared that the defendants knew very little concerning the oil they were shipping. Professor Abel, F.R.S., Professor Roscoe, F.R.S., Colonel Boxer, F.R.S., Superintendent of the Woolwich laboratory, gave evidence as to the nature of the material. By their evidence it was shown to be a highly explosive substance, the explosion being excessively rapid and unaccompanied by smoke, and it is produced by heat. Professor Abel stated that the greater the quantity of oil the lower would be the degree of temperature necessary to explode it, and having in experiments exploded 12 to 20 drops by keeping them for six hours daily at a temperature of 180°, he had arrived at the conclusion that a temperature of 110° to 130° would explode the quantity contained in one of the cases. It appeared that the commercial article, being far from pure, contained a certain quantity of free acid, which generated a gas and produced decomposition, which increased the heat, and the decomposition again was increased with the temperature, and all this tended towards explosion. Moreover when the compound became saturated with this gas it became increased in bulk, and its pressure against the sides of the case became stronger, rendering it more liable to be exploded by concussion. To the oil and to the operation of these qualities in it they did not hesitate to assign the explosion, and Professor Roscoe stated that one case of this oil exploded would have destroyed the *European*. Colonel Boxer proved that it was practically impossible to explode a great quantity of percussion caps at once, for, although the explosion of one extended to the few immediately surrounding it, it never went further, and he produced a box of caps upon which he had let a hundredweight fall from a height of 6ft., and it appeared crushed and out of shape, but the caps were unexploded. Moreover, he had put two ounces of gunpowder into the centre of 2,000 caps in a cylinder and placed the whole in a packing-case and exploded the powder. One-third of the caps only were exploded, and the others were untouched. The mode of clearing the composition out of caps, when it is necessary to do so, is by shovelling 20,000 at a time into a heated oven; there is no explosion, and a minute at least elapses before the composition is consumed. The result of all this is that caps will not explode in a body and are not practically dangerous, and in consequence, the practice is to issue all caps from Woolwich, packed in the middle of the packages of small ammunition; and no case of accidental explosion has ever occurred. For the defence, it was contended that the explosion might have been caused by torpedoes to be used by Chili against Spain, loaded amongst the cargo without the owners' knowledge. The jury found the oil to be the cause of the explosion.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Monatsbericht der königlich-Preussischen Akademie der Wissenschaften. December, 1866.

PATENTS.

Communicated by Mr. Vaughan, F. C. S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1212. E. Guenin, Henrietta Street, Covent Garden, Middlesex, "Improvements in the preparation and application of mustard for curative purposes." A communication from P. Rigollot, Paris.—Petition recorded April 26, 1867.

1549. C. Sanderson, Worksop, Nottinghamshire, "Improvements in the manufacture or melting of cast steel."—May 24, 1867.

1583. W. Mitchell, Northwold, near Brandon, Norfolk, "An improved food for sheep and other animals.'—May 28, 1867.

1628. A. G. Schaeffer, Gloucester-street, Newcastle-on-tyne, "Improvements in obtaining increased light in the combination of illuminating matters."—June 1, 1867.

1635. W. H. Richardson, Glasgow, N.B., "Certain improvements in the manufacture of iron and steel, and in the means or apparatus for effecting the same."—June 3, 1867.

1646. E. Meldrum, Bathgate, Linlithgow, N.B., "Improvements in the purification of paraffine."—June 4, 1867.

1655. G. White, Queen Street, Cheapside, London, "Improvements in the manufacture of hydrate and carbonates of soda."—A communication from F. Biall, Turin, Italy.—June 5, 1867.

NOTICES TO PROCEED.

325. J. Wright, and T. Cobley, Copthall Court, Throgmorton-street, London, "Improvements in the treatment of ores of lead for the purpose of obtaining salts and colours of the same."

337. J. Graham, Manchester Road, Warrington, Lancashire, "Improvements in the manufacture of spelter from zinc ashes and refuses, obtained when coating iron with zinc."—Petition recorded, February 6, 1867.

344. G. E. Pain, High-street, Camden Town, and C. Corry, Dean-street, Soho, Middlesex, "Improvements in the preparation of oils for luminating, lubricating, and other purposes for which they may be applicable." February 7, 1867.

1412. A. A. Bonneville, Rue du Mont Thabor, Paris, "An improved washing powder." A communication from L. Lacalm, and B. A. Gayot, Aubin, France.—Petition recorded May 13, 1867.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1412. H. A. Bonneville, Rue du Mont Thabor, Paris, "An improved washing powder." A Communication from L. Lacalm, and B. A. Gayot, Aubin, France.—Petition recorded May 13, 1867.

1617. F. W. Dolman, Jermyn-street, St. James's, Middlesex, "A new or improved method for obtaining an essential oil applicable as a curative agent or medicine, in the treatment of inflammatory joint diseases, rheumatism, sprains, bruises, and similar ailments." A communication from L. Jamieson, Buxar, Bengal, India.—May 31, 1867.

1712. J. Graham, Banford, Gilford, Down, Ireland, "An improved mixture or composition for bleaching vegetable fibres."

1713. H. Fletcher, Old Hall-street, Liverpool, "Improvements in the manufacture of artificial fuel."—June 11, 1867.

1728. A. M. Clark, Chancery Lane, "Improvements in the manufacture and treatment of white lead, and in apparatus connected therewith."—A communication from R. G. Hatfield, New York, U. S. A.—June 12, 1867.

1747. J. Onions, Devon Place, Newport, Monmouth, "Improvements in the manufacture of steel."

1748. G. M'Kenzie, Glasgow, N.B., "Improvements in the manufacture of illuminating gas."—June 15, 1867.

1803. H. K. York, Cardiff, "Improvements in the manufacture of steel."—June 20, 1867.

1819. G. Dickie, Kilwinning, Ayrshire, N.B., "Improvements in the manufacture of illuminating gas."—June 21, 1867.

1836. J. K. Field, Upper Marsh, Lambeth, Surrey, "Improvements in the manufacture of candles."—June 24, 1867.

1845. J. Webster, Birmingham, "A new metallic zinc paint."

1846 J. Crow, West Ham, Essex, "Improvements in the manufacture of illuminating gas from gas tar oil, or from gas tar."

1850. L. Brunetti, Rovigno, "An improved process of embalming and preserving animal substances from decay, for anatomical purposes."—June 25, 1867.

1886. C. O. Heyl, Berlin, "An improved method of, and apparatus for, making sulphuret of carbon."

1888. J. C. Sellars, Birkenhead, Cheshire, "Improvements in the utilisation of a certain waste material obtained in the manufacture of hydrocarbon liquids."—June 28, 1867.

1900. A. M. Fell, West Calder, Midlothian, N.B., "Improvements in purifying or preservative compounds to be applied to the fleeces or skins of sheep and other animals."

1905. W. H. Richardson, Glasgow, N.B., "A certain improved mode of manufacturing iron and steel."—June 29, 1867.

1950. A. E. Herrmann, Mincing Lane, London, "An improved lubricating compound." A communication from H. Waltjen, Bremen.—July 3, 1867.

2006. G. Gabillon, Rue Joquelet, Paris, "A process to prepare and preserve paper and tissues with a solution of per-chloride of iron, intended for stopping the bleeding of wounds."—July 9, 1867.

2034. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in the manufacture of refined sugar." A communication from E. P. Eastwick, Baltimore, Md., U. S. A.—July 11, 1867.

2046. J. Hargreaves, Appleton-within-Widnes, Lancashire, "Improvements in the manufacture of steel and soft iron from cast iron."

2055. A. E. Herrmann, Mincing Lane, London, "An improved compound to be used for igniting fires." A communication from H. Waltjen, Bremen.—July 12, 1867.

2100. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in the treatment and purification of oils." A communication from F. Asselin, Paris, France.—July 17, 1867.

NOTES AND QUERIES.

Stearic Acid in Paraffin.—Sir,—Is there a test for the presence of stearic acid in paraffin?—X.

Oxidation of Aniline.—Sir,—I should feel obliged to any of your readers who would give me the name and formula for the crystals resulting from the action of bichromate of potash on an acid solution of sulphate of aniline.—$C_{12}H_7N$.

Wires for Micrometers.—Sir,—If any of your ingenious readers can suggest anything which can be used for the purpose of micrometer wires for the microscope, they will confer a favour on the undersigned. At present spider threads, fine platinum wire, and diamond marks on glass are used, but they are all open to objections.—O. Ramsbottom.

Nitrogen.—Sir,—I require absolutely pure nitrogen gas for some experiments. I have instituted a few trials of different methods which appear likely to be successful, but it has occurred to me that, perhaps, a few lines from one of your correspondents may save me the trouble of further investigation. I may state that the purpose for which I require the nitrogen makes me anxious not to prepare it from air. Is there any way of liberating it from a solution or mixture so that the amount and velocity of the supply may be varied at will?—Theta.

Hardening Steel.—Sir,—It has recently been mentioned that filemakers at Sheffield prefer, for hardening their steel goods, water that has been for a long time in use. They say "old water hardens much better than new water;" and amongst the acts occasionally indulged in by workmen against their employers, that of making a hole in the hardening tank and letting the water run away, is considered to inflict injury for some considerable time. Is there any foundation for this opinion?—A Sheffield Blade.

Commercial Testing of Aniline Colours.—Sir,—The ordinary method of determining the value of these colours, viz, dyeing swatches of equal weight and of equal quantities of the various samples in question, is quite satisfactory for reds and blues, but fails completely for purples, violets, and all intermediate shades. The reason is that these colours, instead of being homogeneous, are now frequently made by mixing an ordinary "magenta" with *bleu de Lyons* in the required proportions, or, in other cases, by adding to a violet or purple colour a little magenta or aniline blue, to alter the shade according to wish. Now, a mixed colour of this kind may dye a swatch in the most satisfactory manner, but when used in the large scale the goods first put into the pan and those entered last will have quite different shades, owing to the unequal affinities of the colours for the fibre, and to their different behaviour with the other substances present. The method which I employ to determine whether an aniline violet is homogeneous or a mere mixture, is the successive operation of different solvents. Thus a sample of this nature was treated with hot water and filtered. The filtrate exactly resembled a solution of common magenta in hot water, and gave a worsted the colour which such a solution would produce. The residue, insoluble in water, was then dissolved in alcohol, and was found to be an ordinary aniline blue. If a mixed colour is dissolved in spirit and diluted with water, a drop of the liquid let fall upon white blotting paper will exhibit concentric rings of colours.—W.

Stearic Acid in Paraffin.—Sir,—In reply to your correspondent "X's" query in last week's Chemical News (Amer. Reprint for October, 1867), I can recommend him to try Wagner's test. Dissolve the suspected paraffin in boiling alcohol, and add to it an alcoholic solution of acetrate of lead. If stearic acid be present a white precipitate will fall of stearate of lead, but if the paraffin be pure no precipitation will take place. I can speak from experience as to the value of this process.—B. Hoffman.

Wires for Micrometers.—Sir,—I think perhaps the best thing your correspondent, "O. Ramsbottom," can use for the above purpose is asbestos. This was suggested many years ago by Professor Wallace, who states that fibres of this substance of the 1-3000th of an inch in diameter give a line beautifully even under the microscope and of considerable capacity; the subdivision of the substance can be carried to almost any degree of minuteness.—J. S. S.

Nitrogen, Preparation of.—Sir,—"Theta" will probably find the following plan answer his purpose:—Half fill a tubulated retort with dry nitrate of ammonia. By means of a wire passing stiffly through a cork in the tubulus suspend a piece of zinc so that it can be moved up and down at will. Fuse the nitrate of ammonia by heat, and then push the zinc down into it. Nitrogen and ammonia will be evolved, and the latter can be absorbed by collecting over water or by passing through Woulff's bottles containing water and dilute acid. By adjusting the height of the zinc and the temperature of the salt the disengagement of gas may be varied as desired.—S. Peterson.

Picric Acid.—Sir,—Out of the many works on chemistry that I have, besides the last seven volumes of the Chemical News, I have not in them all a good process for making picric acid. All the processes that one reads are thus:—Picric acid is formed by acting on carbolic acid with nitric acid, assisted by a little heat. Now, what I want to know is, the proportions of carbolic acid and nitric acid, and the strength of the nitric acid, and the degree of heat, and the length of heat, and the length of time that it has to be heated; or, in other words, a good process for making it. If you can give me the above information through the News, I shall feel extremely obliged.—S. R.

Nitrogen, Preparation of.—A correspondent informs us, in answer to the query on this subject, that the best way to prepare nitrogen is to react on dilute ammonia with bromine. The ammonia is to be put into a tubulated retort, or Woulff's bottle, and the bromine poured in through a funnel-tube reaching to the bottom. Nitrogen comes off freely, and may be collected over water. No bromide of nitrogen is formed. The product is bromide of ammonium.

Oxalate of Cerium—Silicide of Aluminium.—Sir,—Could any of your correspondents inform me what remains on igniting the oxalate of cerium, and how to obtain silicide of aluminium?—C. R. N. P.

A Specific Gravity Problem.—Sir,—Might I, through your valuable column of Notes and Queries, ask assistance in the following case:—In examining some meteoric iron I found its sp. gr. (using 50 grains) to be 6·1, but as this iron was intimately mixed with olivine, I afterwards dissolved out the iron in acid, and found that 20 grains olivine were left behind, which had the specific gravity of 3·2. Now, how can I calculate the true specific gravity of the 30 grains iron actually present? I have no doubt that some of your correspondents can help me in this dilemma.

σιδερος.

Bone Boiling.—Can any of your readers tell me how to destroy the smell arising from bone boiling? or, can they inform me how to utilize size, the result of steaming bones? It is unfit for any stiffening process. If used in artificial manures how can it best be appropriated?—Oss.

Naphtha, ναφθα (No. 399).—This word, in the original Chaldee, signifies *stillare*, to ooze or drop; the true naphtha has been found from the most remote ages exuding out of the earth in several places in Chaldæa. One of the tribes of the children of Israël were the Naphthali (Nephthalim, Rev. vii. 6), inhabiting the shores of the Caspian Sea. No doubt the name of the people was derived from their country producing naphtha.—Septimus Piesse, Ph. D.

Specific Gravity Problem.—Sir,—Your correspondent will find the specific gravity problem solved in the following lines:—Weight of meteoric stone in water:

$$= 50-(50\div6{\cdot}1)=41{\cdot}8$$

Weight of Olivine in Water

$$= 20-(20\div3{\cdot}2)=13{\cdot}75.$$

Subtracting we obtain the weight in water corresponding to the 30 grains of dissolved matter 28·05.

Sp. gr. of matter dissolved out

$$=30\div(30-28{\cdot}05)=15{\cdot}384.$$

F. J. R. C.

Specific Gravity Problem.—Sir,—The following formula will, perhaps, answer the purpose of *Sideros*:—Let A., B., C.; a., b., c. represent the weights (in any given unit) and specific gravities of the compound and its two components respectively. Then assuming the volume of unit of weight of water as the unit of cubic contents, we have:

The cubic content of 1 unit of weight of compound body $\frac{1}{a}$

" " " " A $=\frac{H}{a}$;

" " " " B $=\frac{B}{b}$;

" " " " C $=\frac{C}{c}$;

$$\frac{C}{c}=\frac{A}{a}-\frac{B}{b}=\frac{A\,b-a\,B}{a\,b}$$

$$\therefore c=\frac{a.\,b.\,C}{A.\,b-a.\,B}$$

In the present case the sp. gr. would be

$$\frac{3{\cdot}2\times6{\cdot}1\times30}{(3{\cdot}2\times50)-(6{\cdot}1\times20)}=\frac{575{\cdot}6}{38}=15{\cdot}1458.$$

Lloyd.

Specific Gravity Problem.—Sir,—Your correspondent *Sideros* gives a most singular problem. Either it must be only a hoax or else there is some radical error in his observations. If instead of giving respectively the sp. gr. of the original substance and the remaining olivine, he had simply quoted their weight in water, it would have saved great trouble. But, notwithstanding the difficulty thus put into the question, I answer it according to his proposition, and the results induce me to believe in my first assertion, because iron of such a sp. gr. is preposterous. But here is my calculation, minus the method of finding the statements, which he omitted:—

Weight of the iron and olivine in air (original subst.)......	50 grs.
" " " " " " water....	8·1968
Weight of water equal in bulk to iron and olivine........	41·8032
Weight of olivine in air..................................	20 grs.
" " " water..................................	6·24969
Weight of water equal in bulk to olivine..................	13·75031
Weight of water equal in bulk to iron and olivine..........	41·8032
" " " " " " " olivine..................	13·75031
Weight of water equal in bulk to iron....................	28·05289

$$\frac{\text{Weight of iron in air}\ldots\ldots30}{\text{Weight of water equal in bulk to iron}\ \ 28{\cdot}0528}=1{\cdot}10506=\text{sp. gr. of the}$$

iron according to *Sideros* proposition.—C. H. P.

Manufacture of Size.—Can any of your readers inform me how to manufacture size used for sizing woollen warps, or if there is a treatise on it in any chemical work?—J. Morgan.

Picric Acid.—Sir,—I can give your correspondent "S. R." all the particulars he wants concerning the manufacture of picric acid. You can give him my name and address, if, at the same time, I have his.—B. Sc.

Platinum Metal.—Sir,—On dissolving some waste shreds of platinum I found that a small quantity was insoluble. It was in fine powder with perfect metallic lustre. Can any of your correspondents kindly inform me what it is likely to be?—C. R. N. B.

Preservation of Crystals.—Sir,— If any brother reader of the Chemical News will inform me of a convenient way to preserve fine crystals, or efflorescent substances, and salts which change on exposure to the air, he will confer a favour on —Cassio.

Tannate of Alumina.—Sir,—Is tannate of alumina formed by adding gall liquor to acetate of alumina, settling and filtering? If your correspondent "Effra" wants it for the aniline colours, he will find it to give a good lake by adding the colouring matter to the acet. alumina and precipitating with galls.—C. A.

Dyeing Black.—Sir,—Will you kindly solve me a problem that has troubled me long? Among other things I manufacture inks, and I always find black ink settle a good deal after standing 3 or 4 weeks, in fact, till it is almost clear. One purpose for which I use it is for inking cloth, and I require it to have a thickish body, but not to appear glossy, as when gum is put on, and also to dye cotton in the cloth and appear of a good blue colour. This is my formula:—Bruised galls, 20lbs.; chip logwood, 10lbs.; aqua, 33 galls.; boil 7 hours, strain and add copperas, 4 ozs. to the gallon. Do I put too much iron, or too little, or what is it that causes it to settle? Could you either give me a better formula, or tell me how to improve mine so as to be of a middling thickness and a bluish colour? If you will, I shall ever be thankful to you for so doing.—Bichrome.

Prevention of Dry Rot.—Sir,—As an architect I have felt very much interested in the statement made by Mr. G. Lunge in your paper of the 21st June (Amer. Reprint for August, 1867, p. 97), as to the use of tank waste for the prevention of dry rot, and should much like to give it a trial. But I do not quite understand from Mr. Lunge's letter as to whether the waste is to be in direct contact with the timber, or whether it is to be spread on the ground *under* it. I should be glad, also, to learn how the waste is to be obtained. He would, perhaps, kindly point out one or more alkali works at the east end or other parts of London. —T. H. L.

Specific Gravity Problem.—Sir,—Your correspondent "C. H. P." before writing of the "radical errors" in the observations of others, should be careful to be accurate in his own communications. He has evidently very confused ideas as to the relations between the weight of water equal in bulk to the weight in water of, and specific gravity of, a substance. I think the subjoined is a somewhat simpler solution of the problem in question than those of "F. J. R. C." and "Lloyd," the discrepancy between the three results being due to the difference in the number of decimal places used, and to error in "Lloyd's" calculation.

Weight of water equal in bulk to compound = 50 ÷ 6·1 = 8·1968
Weight of water equal in bulk to olivine = 20 ÷ 3·2 = 6·2496
Subtracting we obtain—
Weight of water equal in bulk to iron = 1·9472
Specific gravity of iron = 30 ÷ 1·9472 = 15·406

As this is about double the true sp. gr. of iron, I assume that *Sideros* has, for the sake of simplicity, given a supposititious example.

Henry Matthews, F.C.S.

Specific Gravity Problem.—Sir,—The different solutions of the above problem must have puzzled *Sideros* almost as much as the problem itself. In that furnished by "C. H. P." "there is some radical error," he having mistaken the weight of an equal bulk of water for that of the body in water, as will appear on comparing his calculation with that of "F. J. R. C." The discrepancy between "F. J. R. C.'s" result and my own is caused by his disregard of decimals beyond the 1st or 2nd place, the remarks with which "C. H. P." was pleased to preface his solution are, as it happens, quite *apropos*, for 15·1458 is an even more preposterous specific gravity than the one which he gives. I should imagine that *Sideros*' specimen of meteoric iron was composed of about 10 grains of olivine and 40 of pure iron, as those numbers will give a more nearly correct specific gravity (7·87) for the iron.—Lloyd.

Specific Gravity Problem.—Sir,—Only this moment returned from the Continent, I have not seen either of your two last numbers before to-day, and hasten to correct a mistake, doubtless of my own. The sp. gr. of the meteoric iron should have been stated at 4·9, not 6·1. For this I must apologise.—Sideros.

Naphtha.—Sir,—The emphatic "no doubt" of your correspondent who replies to the query put in No. 399, is somewhat amusing. The same idea had lurked in my mind for a long time, but I found it wouldn't fit. I can't quote Chaldaic, but we are most distinctly told that naphtali (*not naphthali*) means "my wrestling" (Gen. xxx. 8). This son of Jacob was born at least 350 miles from the Caspian Sea, and it is certainly something new in Scripture history to be told that the tribe inhabited its shores, when it is quite well known their inheritance was much further distant than even this, viz., north and west of the Sea of Galilee! (See Joshua xix. 32-39). I venture to suggest that between the words naphtha and napthali there is no connection whatever.—W. Briggs, Naphtha Distiller.

ANSWERS TO CORRESPONDENTS.

Pharmaceutist.—The substance is incorrectly described as *crystallized*. It is a scaled preparation, to which that term is inapplicable.

M. Meller.—The mineral kindly forwarded by our correspondent unfortunately contains no trace of thallium.

J. W.—Add shellac to the solution of india rubber in naphtha—that will confer on it the desired property.

A Constant Reader.—From what we can gather from your long and involved statement, you have not been careful enough to remove free mineral acids from your solution. This has prevented the complete precipitation of the phosphate, and some having consequently passed through, has complicated the subsequent reactions. You can easily test the correctness of your supposition by trying whether the precipitate which ought to be yttria contains phosphoric acid.

Beta.—The alkaline stearates are very slightly soluble in water.

J. Maxwell.—Use a bath of tin, to which bismuth has been added, until its melting point is reduced to about 439F, cover the bath with paraffin to prevent oxidation (powdered charcoal is of no use), and watch the indications of a thermometer immersed in the melted metal.

Laputa.—A mixture of tallow and black-lead is very effectual as a lubricant for gas taps and metallic rubbing surfaces in general.

J. Jellick.—Leaf-gold is generally about 1-250,000th of an inch in thickness.

C. Charles.—Water your gravel walk with a solution of sulphate of iron, this will in all probability improve its colour.

Effra.—Tannate of alumina may be prepared by grinding together in a mortar equal equivalents of freshly precipitated alumina and tannic acid. Wash and dry spontaneously.

B. Y. G.—The best thing to remove grease stains from silk is ether. If you use methylated the expense will be trifling.

E. J.—The patent was taken out on March 2, 1862. See the Chemical News for July 26, 1862, p. 55.

A Bee.—Permanganic acid is volatile, and may be distilled with caution, but the operation is not unattended with danger, as it sometimes explodes.

A Reader from the first.—The crystals have been examined and prove to be acetate of morphia. The quantity you name is a highly dangerous dose.

C. Porter.—The best enamel to use is boro-silicate of soda. This is not attacked by vinegar, salt, or other ingredients used in cooking. The silicate of lead, which is sometimes used as an enamel, gives up its lead to many liquids. It should therefore be carefully avoided in manufacturing utensils for the kitchen.

Artist.—Constant white is the trade name for sulphate of baryta.

Engineer suggests that some boiler explosions may be caused by the annular discharge of steam, sometimes attracting the safety valves to their seats, and thus obstructing the escape; in the same way that a strong blast of air discharged from a pipe within a short distance of a flat surface, will not repel, but will attract any object placed in the intervening space.

F. H.—The vapour of bisulphide of carbon, constantly inhaled, is said to produce temporary insanity amongst workmen

B.R., U.S.A.—The metal erbium certainly seems to be an elementary body, and not a mixture of yttrium and didymium. Few chemists have worked on the subject, owing to the rarity of the minerals containing these earthy bases.

Quæsitor asks where stoneware vessels capable of holding 1,000 gallons can be had of the best quality, capable of resisting the action of strong commercial hydrochloric acid at 200 to 300F. He cannot do better than apply to Messrs. Cliff and Co.

ANALYSIS OF BLISTER STEEL.

BY DAVID FORBES, F.R.S., ETC.

Very few analyses of blister steel are to be met with in any of the treatises on metallurgy, and even in Dr. Percy's recent work on the metallurgy of iron and steel, no analysis is to be found of this truly national product. Under these circumstances therefore, the following analysis of blister steel converted in Sheffield from bar-iron of Swedish manufacture, may be considered as worthy of being recorded.

In making this analysis the portion selected for examination was obtained in a sufficiently divided state by chipping off the bar with a cold chisel, since it was found that no reliance could be placed in filings, which even if produced by the best files were always largely contaminated by the *debris* of the file itself; the determination of the constituents was made as follows:—

Determination of the total amount of Carbon.—77.91 grains of the steel in the form of such chippings, were allowed to remain (about ten days) in a cold solution of 200 grains pure chloride of copper, until no undissolved steel remained behind; the residue was then well washed by decantation, dried, mixed with 100 grains of pure oxide of copper, and burnt in a current of purified dry oxygen gas, at a heat sufficient to soften the Bohemian glass tube. The carbonic acid collected as usual in a potash apparatus amounted to 2·08 grains, or equivalent to 0·729 per cent. carbon in the steel.

Determination of the Sulphur.—107·58 grains were placed in a flask provided with a safety-funnel, and digested (for twenty-four hours) in the cold with strong hydrochloric acid; the gas evolved was passed through a solution of pure chloride of zinc supersaturated with ammonia; the iron being all dissolved, the zinc solution was boiled with nitric acid in some excess, nearly neutralized by ammonia to prevent any solvent action from excess of acid, and precipitated by a solution of pure chloride of barium,—0·04 grains sulphate of barytes were obtained, equivalent to 0·005 per cent. sulphur in the steel.

Determination of the Silicon and uncombined Carbon.—The solution from above was evaporated in a water-bath to dryness, re-dissolved in water with some hydrochloric acid, and filtered from the insoluble silica and graphite; these latter were washed off the filter into a silver basin, in which they were boiled with potash, which dissolved out the silica, leaving the graphite, which was collected on a filter, washed, dried, carefully scraped off filter, and after drying at 250° F., weighed 0·11 grains, equivalent to 0·102 per cent. uncombined or graphitic carbon. The potash solution of silica was supersaturated with hydrochloric acid, evaporated to dryness, and the residue treated with water rendered acid by hydrochloric acid. The silica was then filtered off and determined as usual, being 0·06 grains, or equivalent to 0·0304 per cent. silicon in the steel.

Determination of the Manganese.—The acid filtrate, after separating the graphite and silica by filtration, was now nearly neutralized by ammonia, and then treated with carbonate of barytes in excess, filtered, and the filtrate precipitated by sulphide of ammonium, the sulphide of manganese mixed with some sulphate of barytes was then treated with weak sulphuric acid, filtered, and the manganese precipitated by carbonate of soda as usual, affording 0·18 grains manganosomanganic oxide, or equivalent to 0·12 per cent. manganese in the steel.

Search for Phosphorus.—52·75 grains of the steel treated precisely according to Abel's directions (Chemical News, vol. vi. p. 133, *Eng. Ed.*), afforded no trace of ammonic phosphate of magnesia. 73·28 grains examined by Spiller's process (Chemical News, vol. xiii. p. 170, *Eng. Ed.*), gave the same negative result; and, lastly, 48·07 grains tested by Eggertz's method by molybdate of ammonia, did not afford any trace of phosphorus.

Determination of Iron.—The amount of iron present was estimated as loss. The percentage results will be as follows:—

Carbon combined	0·627
——— graphitic	0·102
Silicon	0·030
Phosphorus	0·000
Sulphur	0·005
Manganese	0·120
Iron	99·116
	100·000

ON THE USE OF POTASSIC CHLORATE IN QUALITATIVE BLOWPIPE EXPERIMENTS.

BY JOHN LANDAUER.

I communicated in No. 399 of the Chemical News (*Amer. Reprint, Sept.* 1867, *p.* 159), as the result of many experiments, a method of detecting manganese by means of potassic chlorate and the blowpipe.

I have continued these experiments, and convinced myself that this salt may be used with advantage for the detection of many oxides by means of the blowpipe, inasmuch as it leaves nothing to be desired as regards readiness and delicacy of execution. The delicacy of the test especially is greatly augmented by the fact, that the originally white salt assumes the respective colours.

The action of the potassic chlorate is, of course, that of energetic oxidation, caused by the evolution of oxygen at a high temperature. I find it most convenient to employ glass tubes, not too thick, in dimensions of about 15 centimetres long by 5 millimetres in width, and closed at one end; in these is introduced a small quantity of the chlorate, together with the substance to be examined; heat is applied gradually, at last with the help of the blowpipe, until no more oxygen is given off. The reaction is then completed, and the colour of the flux is examined.

I give in the following table some of the more delicate reactions, reserving a more complete investigation, the results of which will shortly be published in this journal:—

Iron	Flesh colour
Lead	Yellowish brown
Copper	Black or greyish black
Cobalt	Blue (in certain cases black)
Manganese	Purple
Nickel	Black (Ni_2O_3.)

ON THE

UTILISATION OF THE WASTE PRODUCTS OF THE MANUFACTURE OF COAL GAS.

BY DR. LETHEBY.

(Continued from page 170, Amer. Reprint Chem. News.)

Carbolic Acid Colours.

Four or five dyes have already been produced from this compound, namely, *rosolic acid* or *aurine*, *peonine* or *coralline*, *azuline*, and *picric acid.*

Rosolic acid is contained in coal-tar, as was first demonstrated by Runge in 1834, who extracted it from the dark red-brown residual product of carbolic acid by means of spirit; and on treating the solution with caustic lime, he separated a brown compound (brunolate of lime), and obtained a red solution (rosolate of lime), from which he precipitated the rosolic acid as a dark red powder by the aid of acetic acid. Other observers, as M. Tschelnitz in 1857, and Dr. Hugo Müller still later, noticed that the common carbolate of lime of commerce became red on exposure to the air, and that this was due to the formation of rosolate and brunolate of lime; but we are indebted to Dr. Angus Smith, and more recently to M. Jourdan, for an explanation of the changes which thus take place in carbolate of lime, and for suggestions for a process for making the dye on a commercial scale. They found that when the vapour of carbolic acid is passed over a hot mixture of soda and peroxide of manganese, or peroxide of mercury, oxygen is absorbed and rosolic acid produced, thus:

$$\underbrace{2C_{12}H_6O_2}_{\text{Carbolic acid.}}+O_2=\underbrace{C_{24}H_{12}O_6}_{\text{Rosolic acid.}}$$

The residue yields to water a rich solution of rosolate of soda, from which the rosolic acid can be obtained by precipitating by means of acetic acid.

The production of acid commercially has been accomplished and patented by Messrs. Guinon, Marnas, and Bonnet. They mix together about 23 parts, by weight, of carbolic acid, 10 to 20 of oxalic acid, and from 7 to 14 of commercial sulphuric acid, and heat them for three hours or until the desired colour is obtained. The product is well washed with water to remove the excess of acid, and the residue, which is impure rosolic acid (*aurine*), is a soft pitchy material with a green shade of cantharides; but as the acid is insoluble in water and cannot well be fixed upon fabrics, the patentees have converted it into a new compound, named *peonine*, by incorporating nitrogen with it.

Peonine or *coralline* is produced by heating 1 part of the rosolic acid with 2 parts of ammonia of commerce, for three hours, in a closed metallic vessel at a temperature of 270° Fahr. The product is a thick liquid of considerable tinctorial power, and which gives with acids a deep red insoluble or fast colour, which may be so applied to silk, wool, and other textile fabrics.

Azuline, as I have already stated, is a blue colour, produced by heating 5 parts of peonine with 6 or 8 of aniline, and keeping them at nearly the boiling-point for several hours.

Picric acid, or *carbazotic acid*, or *trinitrophenic acid*, is obtained by oxidizing carbolic acid with nitric acid. It was formerly procured by a like treatment of indigo and the yellow resin (*Xanthorrhea hastilis*) of Australia, and also by the action of nitric acid upon the coal naphtha, which distils between 300° and 400° Fahr.

When carbolic acid is cautiously dropped into strong nitric acid it is attacked with great violence and with a hissing noise, as you may observe; and, according to the strength of the acid, there are produced one or more of the following substitution compounds:—

Carbolic acid	$C_{12}H_6O_2$
Mononitrophenic acid	$C_{12}H_5NO_4O_2$
Binitrophenic acid	$C_{12}H_4(NO_4)_2O_2$
Trinitrophenic acid	$C_{12}H_3(NO_4)_3O_2$

If the acid be strong enough, the last compound is alone produced, and when the mixture cools it deposits crystals of picric acid. These are purified by dissolving them in water, neutralising the solution with carbonate of soda, evaporating, and crystallizing. The crystals of the soda salt yield, when they are decomposed with dilute sulphuric acid, fine yellow, pearly looking crystals, or plates of picric acid. They are soluble in from 80 to 90 parts of cold water, and they possess considerable tinctorial power—a grain of acid in 300,000 grains of water will give a moderate shade of yellow to 1000 grains of silk. The colour is best applied with a mordant of alum and cream of tartar; cotton fabrics do not retain the colour, and hence it becomes a test for such tissues when mixed with wool or silk. The solution is very bitter, and, as it is not a poisonous compound, it has been thought that it might be used instead of hops for beer. It forms yellow salts with the alkalies, and with metallic oxides, and most of them are highly fulminating or explosive when heated.

If picric acid is submitted to the action of reducing agents it produces red colours of great beauty; thus *picramic acid* is formed when the acid is reduced by means of a hot solution of protosulphate of iron (Wöhler), or by the aid of sulphuretted hydrogen or sulphide of ammonium (Girard).

$$\underbrace{C_{12}H_3(NO_4)_3O_2}_{\text{Picric acid.}}+6HS=\underbrace{C_{12}H_5(NO_4)_2NO_2}_{\text{Picramic acid.}}+4HO+S_6$$

The acid thus obtained is in the form of brilliant ruby-red crystals, which are soluble in alcohol and ether, and slightly soluble in water.

Isopurpuric acid is another red product of picric acid. It is procured from it by the process of M. Hlasiwetz, which consists in dissolving 2 parts of cyanide of potassium in 4 of water, and when it is heated to a temperature of 140° Fahr., adding little by little a solution of 1 part of picric acid in 9 of water. The liquid evolves ammonia and prussic acid, and, on cooling, deposits an abundant crop of crystals. These are washed with a little cold water, and then dissolved in boiling water to which a little carbonate of soda has been added; as the solution cools, it yields tolerably pure crystals of isopurpurate of potash. They have a red-brown colour by transmitted light, and a green metallic by reflected. By substituting ammonia for potash, as by dissolving the crystals in boiling water and adding sal-ammoniac, there are formed, as the solution cools, beautiful red crystals of isopurpurate of ammonia, which is isomeric with the brilliant red dye called *murexide*, and which, but for the cheaper forms of aniline colours, would have been an important dye; for it gives to silk and wool, when mordanted with corrosive sublimate, a magnificent purple rivalling the purple of Tyre; and with a mordant of zinc it produces a brilliant yellow. The colours are very fast, but they will not resist the action of the sulphurous acid so constantly found in the atmosphere of towns.

We know but little of the homologues of carbolic acid—namely, cresylic acid ($C_{14}H_8O_2$)—and the higher members of the series, which may, perhaps, be capable of yielding corresponding coloured compounds.

Naphthaline Colours

have not yet been successfully produced, although many attempts have been made to utilize it in this way; indeed, as far back as 1858, Strecker drew attention to the similitude of chloroxynaphthalic acid and the red colouring constituent of madder (alizarine), there being required only the substitution of hydrogen for the chlorine to change it into madder red; and in 1861, M. Z. Roussin announced that he had actually converted naphthalin into alizarine. His process was first to act on naphthaline with nitric acid, and so change it into binitronaphthaline, thus:—

$$\underbrace{C_{20}H_8}_{\text{Naphthaline.}}+2HNO_6=\underbrace{C_{20}H_6(NO_4)_2}_{\text{Binitronaphthaline.}}+4HO$$

This is a crystalline body, which he next dissolved, little by little, in concentrated sulphuric acid. The mixture was then heated to a temperature of 392° Fahr., and small portions of granulated zinc were cautiously added to it. After a time sulphurous acid began to be evolved, and the nitronaphthaline was slowly converted into a red colouring matter, which he thought was alizarine. The change appeared to be as follows:—

$$\underbrace{C_{20}H_6(NO_4)_2}_{\text{Binitronaphthaline.}}+H_8=\underbrace{C_{20}H_6O_6}_{\text{Alizarine.}}+2NH_3+2HO$$

By diluting the mixture with 8 or 10 times its bulk of boiling water, and quickly filtering, the solution yielded as it cooled, brilliant red crystals. But they differ from alizarine in many essential particulars, especially in not giving the purple and chocolate tints, as alizarine does, with iron and alumina mordants.

Mr. Perkin has also devoted attention to this subject, but his labours have not been very successful.

Naphthalamine is a compound which bears the same relation to naphthaline that aniline does to benzole, and it is made by somewhat similar transformations. Messrs. Calvert, of the Tower Chemical Works, have produced it very largely, in the hope that, by oxidation in the same way as aniline and toluidine are oxidised, colours might be obtained. In this manner Mr. Brunner produced in Mr. Calvert's laboratory a very fine purple, by heating it with arsenic acid. M. Du Wildes obtained a like result with the nitrates of mercury; and M. Roussin has shown how fabrics may be dyed of a red colour by acting on muriate of naphthalamine with nitrate of potash, and how a violet-red tint may be obtained by heating a mixture of naphthalamine and dry bichloride of mercury in a sealed tube, at a temperature of 356°, for many hours; and by heating a mixture of muriate of naphthalamine and protochloride of tin to a temperature of 472° Fahr. The purple-red colour is in both cases insoluble in water, but soluble in alcohol, and may be thus used as a dye. Messrs. Guinon, Marnas, and Bonnet have also proposed to use it in the place of aniline for the production of a blue colour; but I am not aware that any of these processes have been put into actual practice.

And now in conclusion, as I have been compelled, for want of time, to deal very briefly and generally with this subject, I will merely state that those who are anxious to pursue the matter further will find many memoirs on the subject, to which they may refer with advantage. In this country there have been published the valuable report of Dr. Hofmann, at page 119 of the chemical section of the "Reports of Juries" on the International Exhibition of 1862, and the "Lectures by Dr. Calvert on Coal-Tar Colours, in Relation to Dyeing and Calico Printing;" and on the Continent the following have been published:—

1. "Examen des Matières Colorantes Artificielles dérivées du Goudron de Houille." Par E. Kopp. 1861.
2. "Matières Colorantes dérivées du Goudron de Houille." Par Ad. Wurtz. 1862.
3. "Manufacture and Properties of Aniline Colours, and the Bodies used in their Preparation." By MM. Depouilly Brothers. 1866. Chemical News, vol. xiv., pp. 77, 89, 157, *Eng. Ed.*
4. "Technologie des Anilins." "Handbuch der Fabrikation des Anilins, und der von ihm derivirten Farben." M. Reimann. 1866.

In addition to which there are numerous papers on the subject in the scientific journals of the last six years, several of which have appeared, either in full or in abstract, in the *Journal of Gas Lighting.*

ON THE ABSORPTION OF GASES BY CHARCOAL.

The following letter from Dr. R. Angus Smith, F.R.S., to Dr. J. P. Joule, F.R.S., has been forwarded to us:—

"My dear Joule:—You asked me about my experiments on the absorption of gases by charcoal. I certainly seem to delay them, but I have little spare time. In 1848 I illustrated the oxidising power of porous bodies, referring chiefly to sand. In 1862, when speaking of the absorption of gases by charcoal, I ventured to say that the physical and chemical action could not be separated. I have been anxious to obtain more direct evidence.

"I had worked a good deal with the mixed gases, but lately thought it better to return to the simple, although unwilling to question results got by others. Five of these gases have been tried, and they are found to be absorbed by charcoal in whole volumes, and not in fractions of a volume, hydrogen being taken as one. In three cases hydrogen, oxygen, and carbonic acid, the numbers are 1, 7·99 and 22·05, extremely exact volumes, with a relation the same as our ordinary atomic weights. Saussure's numbers treated thus give 5·3 and 20, that for nitrogen being 4·2.

"It is only by taking the average of many experiments that these results have been obtained, but, in doing so, every one has been added without selection. The numbers from which the averages are obtained diverge so much that I suppose others have not thought of obtaining anything definite. This is caused by the difficulty of finding perfectly uniform charcoal.

"I have not found the other numbers to be the same as the equivalents, although still whole. Equivalents promise here to enlarge their bounds. I cannot believe that these numbers can be the results of any accident. They must be distinguished from chemical equivalents by weight.—I am, yours, &c.

"R. Angus Smith.

"Manchester, June 17, 1867."

ON THE PRACTICAL LOSSES OF SULPHUR, ETC., IN THE VITRIOL MANUFACTURE.

BY CHARLES R. A. WRIGHT, B.SC.

The following table, calculated by interpolation from Bineau's results (*Ann. Chem. et Physique*, iii. xxiv. 341), may be useful to manufacturers and others in calculating the value of sulphuric acid of a given density according to Twaddell's hydrometer, at a given temperature.

At 15 deg. Centigr.		Diminution in density for 1 deg. C. above 15 deg. C.	Percentage of SO_4H_2.	Difference for 1 deg. T.	Percentage of SO_3.	Difference for 1 deg. T.
Deg. T.	Sp. Gr.					
68·52	1·8426	0·192	100·00	..	81·63	..

The first column indicates the strength as given by Twaddell's hydrometer at a temperature of 15°C., and the second the corresponding sp. gr.

The third shows the fraction of a degree Twaddell to be added to the observed strength for each degree centigrade that the acid is above 15°C.; or to be subtracted for each degree below 15°C.

The fourth indicates the percentage of SO_4H_2, corresponding to the density at 15° given in the first and second columns; and the fifth, the differences between the numbers in the fourth, used for calculating the amount to be added on for fractions of a degree Twaddell.

The sixth and seventh columns indicate the quantities of SO_3 corresponding to those of SO_4H_2 in the fourth and fifth.

Thus, to find the percentage of SO_4H_2 present in acid in which a hydrometer marks 154°·5 T. at a temperature of 25°C.

154°·5 T. at 25°C. correspond to 154·5 + 10 × 0·183,
or 156°·3 T. at 15°C.
Acid at 154°T. at 15°C. contains 83·30 per cent. of SO_4H_2
Add on for 2°·3 T.: 2·3 × 0·53 = 1·22 " "

Percentage required .. 84·52

To find the percentage of SO_3, in acid of 121°·1 T. at 9° C.

121·1° T. at 9° C. correspond to 121·1 − 6 × 0·174, or 120·06 at 15° C.

Acid of 120° T. at 15° C. contains 56·06 per cent. of SO_3.

Add on or 0°06 : 0·06 × 0·35 = 0·02

Percentage required..........56·08

An acid of high specific gravity is more likely to contain lead sulphate, as the effect of temperature in altering the density is greater the stronger the acid, and as there is but little difference in density for a considerable difference in percentage with strong acid, it is evident that the amount of SO_3 or SO_4H_2, can only be approximately determined in strong acid by the aid of the hydrometer; taking also into consideration the fact that glass hydrometers, as usually sold, are rarely correct to within 0·5° T., and are frequently more erroneous, it may be pretty safely stated that the value of any acid of above 160° T cannot be estimated at all accurately by the hydrometer.

The amount of acid theoretically obtainable from any given ore is readily calculable by the following simple formulæ:—

From one part of sulphur ore containing x per cent of sulphur there is theoretically obtainable—

(1) of acid containing m per cent. of SO_4H_2

$$2{\cdot}5 \times \frac{x}{m} \text{ parts.}$$

(2) " " n " SO_3

$$3{\cdot}0625 \frac{x}{n} \text{ "}$$

Thus from a kilogramme of ore at 32 per cent. of sulphur there is theoretically obtainable of acid at 135° T. (containing therefore 75·00 per cent. of SO_4H_2)

$$2{\cdot}5 \times \frac{32}{75} \text{ kilogrs.} = 1{\cdot}067 \text{ kilogrs.}$$

and from a kilogramme of pure sulphur there is obtainable of acid at 154° T. (containing 68 per cent. of SO_3)

$$3{\cdot}0625 \times \frac{100}{68} \text{ kilogrs.} = 4{\cdot}504 \text{ kilogrs.}$$

Chemical Laboratory, St. Thomas's Hospital, S.

PHILOSOPHICAL CONCEPTIONS OF CHEMICAL PHENOMENA.

The "fundamental definition" of a chemical phenomenon lately advanced by Sir Benjamin Brodie, to the effect that "A chemical phenomenon is an operation on the unit of space, the result of which is a weight," has strongly directed the attention of chemists to the primary conceptions on which the philosophy of their science is based.

At such a juncture it cannot but be interesting to set in contrast with the above startling philosophical innovation, one of the most clear and powerful expositions extant of the received mode of viewing this abstruse question.

Such an exposition we find in the ninth chapter of the admirable "Introduction to Modern Chemistry" lately put forth by Professor Hofmann in collaboration with Mr. F. O Ward,—"whose well-known powers of lucid composition, and habits of philosophical thought, are traceable," as his illustrious colleague justly observed in his preface, "in every chapter of the work."

We shall the more readily lay these extracts before our readers, because, while specially apposite to the present tenour of chemical meditation, their appearance will redeem the promise made by us, in our first review of this book, to give it a second notice in our columns.

We therefore, without further preface or apology, proceed to lay the following extracts before our readers, merely remarking that we have here and there exercised our editorial privilege of excision and abridgment.

"Thus far," say the collaborating authors, "we have not quitted the domain of experience, of observation; to the *causes* of the remarkable phenomenon we have contemplated, our attention has not yet been turned. Yet the inquiry into the causes of observed phenomena is urged on us by one of the strongest instincts of our intellectual nature. That instinctive curiosity cannot, indeed, be fully satisfied. The first causes of phenomena lie beyond the limited scope of our perceptive and reasoning faculties. The conditions of their existence or production, and their relations of succession and similitude are, indeed, open to investigation; but their intimate nature and prime origin are for us inscrutable mysteries. We may, however, by the aid of imagination, form *hypotheses*, to connect the results of our experiments, and to guide the course of our inquiries. And, though merely speculative hypotheses, dissevered from experimental investigation, are to be deprecated as vain and sterile exercises of ingenuity, hypotheses based upon facts, assisting in their conception, and deriving probability from the number thereof which they connect and explain, besides (and above all) tending to suggest new experiments, deserve to rank among the most valuable aids to scientific research.

"Hypotheses are, of course, to be held provisionally, subject to modification and abandonment, in so far as they may from time to time prove inconsistent with the results of further experimental research. On the other hand, when hypotheses embrace and explain extensive ranges of phenomena, when experiment confirms the results they foreshadow, when successive discoveries raise them higher and higher in the scale of probability, they lose more and more their provisional character, and gradually assume the name and rank of *theories*, till at last they come to be embodied among the recognised doctrines of philosophy.

"The observed phenomena of combination in definite proportions by weight and volume, are susceptible of explanation by a theory in the highest degree probable and suggestive, which comes next in order for our consideration.

"In order to arrive at this theoretical conception, we must ask ourselves, what *is* matter? Of what parts is it composed? How are these constructed and held together? How comes the very same matter, water for example, to present itself sometimes in the solid form, as ice; sometimes in the liquid form, as the same ice when melted; sometimes in the gaseous form, as the same melted ice changed to dry steam by further heating? And, lastly, what happens to matter, what changes does it undergo, when its various elementary forms combine, as we have seen them, to produce bodies having properties wholly different from those of their constituents?

"Setting aside the more transcendental speculations of philosophers upon the nature of matter, let us here select for consideration those hypothetical conceptions of its structure which seem best adapted to connect and explain the results of modern research; and which, by enabling us to comprehend the phenomena we have already witnessed, may also assist us in shaping the course of our further experimental researches.

"Let us, for this purpose, consider the familiar body, *water*, into the nature of which our experiments have already given us some insight; and let us consider it in its three conditions, as ice, as fluid water, and as water-gas or dry steam. What is the first thing that strikes us in looking at them?

"The first thing that strikes us is, that ice, water, and steam manifest two sorts of activity;—one exerted by masses of sensible magnitude, acting through measurable distances of space; the other operating between particles, and through intervals of space, so minute as to be incommensurable.

"The attraction of mass for mass of matter, as manifested in the courses of the celestial bodies, in the movement of falling bodies, and in the pressure of bodies at rest upon the ground, exemplifies the first kind of activity. This is equally observable in the ice, in the water, and in the water gas; for these all possess *weight;* a sensible mass of either reciprocates attraction with the earth, through measurable distances of space.

"The Latin for mass is *moles;* and its modern diminutive, *molecula*, is employed to designate 'a little mass,' that is to say, a material particle of incommensurable minuteness; hence the reciprocal actions of minute particles through insensible intervals of space are distinguished as *molecular*. We may fairly therefore contradistinguish, by the epithet *molar*, the reciprocal actions of measurable masses through measurable intervals of space.

"The means of mechanical comminution at our disposal, our grinding-mills, mortars, and the like, do not carry us beyond the *molar* subdivision of matter. However finely we might grind up ice, for example, if we took care to keep the temperature below freezing point, we should still have masses each consisting of several molecules. For, our finest ice-powder would still consist of very small fragments of solid ice; and if, of this ice-dust, we took the smallest grain, we could, by applying heat, turn it into water, thus proving it to have *parts*, capable of separation, so as to be rendered moveable amongst each other. There is no instance of liquefaction resulting from the mechanical comminution of a solid body. Hence we take it as certain that the most impalpable product of mechanical pulverisation is still a cluster of molecules.

"We are thus enabled to distinguish in matter two kinds of divisibility, *molar* and *molecular;* the former being accomplished by *mechanical* means, and only resulting, even when pushed to its utmost attainable limits, in the production of a molecule-cluster or mass of sensible dimensions, which may be termed a *mole;* while the latter is accomplished by *physical* means (that is to say, by the aid of physical forces, such as heat), resulting in the disruption of the masses or *moles* into their incommensurably minute constituents *molecules.*

"The study of the reciprocal action of material *masses,* or *moles,* constitutes the science of *mechanics;* a science of the deepest interest, abounding in simple and admirable laws, with which, however, we are not at present concerned.

"Turning to the consideration of *molecular* activities, of those which are distinguished by the incommensurable minuteness of the particles of matter, and of the intervals of space, between and through which they take place; and looking once more at the samples of matter before us—at our ice, our water, and our water-gas or steam; we are again, as before, struck with a contrast between two diametrically opposite kinds of activity, one conspicuously manifested in the solid ice, and called *molecular cohesion,* the other especially manifested in the water-gas, and termed *molecular repulsion.* The former force gives to solid bodies their tenacity; to the latter, gaseous bodies owe their extreme tenuity, and the free mobility of their molecules amongst each other."

"In fluid bodies, here represented by our water, we observe these two forms of molecular activity balanced at an intermediate point. The molecules of fluids cohere with considerable force; as we perceive, when a rod is dipped into water, and a bunch of them taken out, sticking to each other, and also to the rod, in the form of a pendent water-drop; but this cohesion is exceedingly feeble as compared with that of the same molecules agglomerated in the solid form in a block of ice. Again, the molecules of fluids are moveable amongst each other; as we notice when water is shaken in a vessel, agitated with a rod, or poured into another glass; but their mobility is far inferior to that of the molecules of gas. In vain should we dip our rod into the gas to take up a drop of it; we should obtain no coherent bunch of gas-molecules, like the pendulous water-drop. And it is precisely to their superior molecular cohesion that fluids owe their inferior molecular mobility as compared with gases.

"This difference of comportment is not surprising when we reflect how much greater are the intervals which separate the molecules of a gas—of our water-gas, for example—than those which intervene between the molecules of the same body in the form of ice or of water."

"What is the nature of the intervals between the molecules of a gas?—are they empty space, or are they filled? and, if so, how, or with what are they filled? That they are not empty spaces we have very good reason to believe, on account of the powerful resilient property manifested by gases when forcibly compressed.

"But what is the nature of this elasticity or resilience—to what power or force is it due?

"Several phenomena point to *heat* as its cause. Heat is the agent by which ice is made to pass, through the fluid, into the gaseous form; and, with every increment of heat, the elastic power of the ice-derived gas augments.

"To the questions, therefore, what is a gas? and with what are the intervals between its molecules filled? succeeds the question, what is heat? This brings us face to face with one of the most ardently-mooted and deeply-interesting philosophical questions of the day. For some, heat is a species of thin ether, vibrating in the manner of light; for others, it is a pure force, having neither parts nor weight; for a third class of thinkers, of late years the majority, heat has no separate existence, but is merely a mode of motion, the result of the vibration of material molecules.

"It is no part of our present task to attempt the solution of this deep and difficult problem. We may content ourselves here with the conception that heat, whatever may be its intimate nature, so operates, when it becomes latent in a gas, as to surround each molecule with a sort of repellent atmosphere which tends to keep it apart from its fellows; and that these molecular force-spheres—or, to employ the Greek equivalent, *dynami-spheres,* more shortly, *dyna-spheres,* when mechanically compressed, counteract the pressure with exactly equal energy, and on the removal of the pressure, restore the gas (other things being equal) to the exact volume it previously possessed.

"It thus stands clearly demonstrated that, if equal volumes of the elementary gas, hydrogen, and of the compound gas, hydrochloric acid, be taken under any given pressure, and the pressure be doubled for each, each becomes reduced to half its former volume, and at the same time acquires double its former resilient force, or elasticity; which it exerts in counterbalancing the pressure from without.

"It stands equally proved that, if equal volumes of hydrogen, and of hydrochloric acid gas, taken at equal degrees of pressure and temperature, be exposed to equal increments or decrements of heat, they undergo equal degrees of expansion and contraction.

"It has been experimentally established as a law, that all true gases, simple as well as compound, comport themselves in sensibly the same manner under like variations of temperature and pressure; whence the inference fairly follows that their molecular structure is the same. Assuming, then, each gaseous molecule to be clothed or enveloped by a resilient dynasphere (as we have termed it), due, in some unknown way, to the influence of latent heat, experiment justifies us in inferring, from the identical comportment of all gases, when exposed to like variations of temperature and pressure, that they all contain, in equal volumes, an equal number of molecules so clothed; and that, as an obvious corollary, the diameter of these gas-molecules (including in that term as well the dynaspheres as their material nuclei) is, under like physical conditions, precisely the same for all gases. To express it more shortly, our unit-volume, or litre, whether of hydrogen, of hydrochloric acid, or of any other gas, simple or compound, is composed of mutually repellent dynaspheric molecules, equal (*omnibus paribus*) as to their *number,* and (consequently) as to their *size.*

"At this point of the inquiry we may advantageously resume the consideration of material divisibility, of which we have already studied two forms or grades, the *molar* and the *molecular;* the former consisting in the mechanical disruption of large masses into small ones, the smallest still possessing sensible magnitude; while the latter is the further disruption, by physical agents, such as heat, of moles or masses, whether large or small, into their constituent molecules; that is to say, into parts contradistinguished from the minutest moles by the fact that they (the said parts) possess no commensurable magnitude at all. In the particular sample of matter which we have selected for study, as being the most familiar of all compounds, we see molecular succeeding to mere molar division, when heat melts comminuted ice into water, and then raises water into invisible steam or gas, by clothing its molecules with the mutually repellent dynaspheres, each dynasphere 1689 times larger than its material nucleus.

"Infinitesimal as this subdivision of matter appears, —inexpressibly minute as we cannot but conceive the material particles to be that form the central nuclei of the dynaspheres of bodies so attenuated and rare as the invisible gases,—we yet know, by experimental proof, that a further comminution of matter is possible; and that, as the smallest mass or mole of any compound may be broken up into its constituent molecules, immeasurably smaller still, so the ultimate molecule itself, however small we may choose to conceive it, is nevertheless still a *compound*, consisting of at least two parts, which, by chemical agency, may be detached from each other, so as to resolve the compound into its elements.

"Here the divisibility of matter, so far as our experimental knowledge extends, reaches its final term. The *elementary* bodies are, as we remember, so called precisely because they resist every agency, mechanical, physical, and chemical, which we can bring to bear in the hope of dividing or decomposing them. We may imagine the two elementary particles which form the compound molecule of hydrochloric acid, for example, to be as small as we please. In this respect we may give the imagination free rein; we may conceive the particle of hydrogen, or of chlorine, to be divided and subdivided as many millions of times as we like,—or rather, until the imaginative power is baffled by sheer exhaustion in the endeavour to push this conception further. No experiment yet made tends to restrict the freest range of our mental faculties in this direction; their only limitation lies in their own finite scope, doubtless more or less extensive in different minds. But, when we have, each of us, thus reached the idea of the smallest elementary particle which it is within the power of the mind to picture, all experience stands opposed to our going still further, and presuming to declare the elementary particles capable of division *ad infinitum*. Not one experimental result can be adduced in support of such an assertion. At this point, therefore, the experimental philosopher arrests his inquiry. Beyond this limit he sees only the dream-land of metaphysical speculation—a region essentially sterile because shut out from cultivation by means of experiment, from which alone can spring the harvest of Truth in the proper sense of the word; having for its foundation natural facts; for its object the study of their relations; for its result the determination of their laws.

"To the metaphysical speculators, therefore, let us cheerfully resign the utter futile and fruitless discussion whether even elementary matter may not be infinitely divisible. It is enough for us to know that, at all events, *we* cannot infinitely divide it, but that, relatively to our powers and purposes, to the limits of our imagination as well as of our experience, the assertion of the infinite divisibility of the elements is one we are not justified in making.

"We thus arrive at the conception of indivisible particles as the ultimate constituents of elementary bodies, and these particles have received the appropriate name of *atoms* (from the Greek word τέμνω, *I cut*, *I divide*, with the privative *a* prefixed in token of negation).

"The addition of this final term completes and enables us to epitomise our view of the threefold divisibility of matter, molar, molecular, and atomic; the first (molar) being performed by *mechanical* means, and resulting, when pushed to its utmost limits, in masses or moles (clusters of molecules) characterised by their possession of sensible magnitude; the second (molecular) accomplished by the agency of the physical forces (heat, electricity, etc.), employed under special conditions for the purpose, and resulting in the production of the dynaspheric *molecules* of which we reasonably conceive compound bodies to consist; the third (atomic) being capable of accomplishment only by agencies, such, and so applied, as to produce *chemical* decomposition, breaking up the incommensurable molecule itself into its elementary particles, which (as just explained) are called *atoms*, because incapable of further disruption or comminution by any means at our disposal.

"This conception of the threefold divisibility of matter, molar, molecular, and atomic, being once clearly understood, and firmly grasped by the mind, we may usefully proceed, in the light which this theory supplies, to compare as to their structure compound with elementary gases. At first view we should be disposed, perhaps, to anticipate as probable, that, while the compound gases would be formed of divisible molecules or atom-clusters, the elementary gases would present no such complexity of structure, but consist merely of separate and indivisible elementary particles. But a little consideration will show us that this view is incompatible with the results of our preceding inquiry.

"Let us, to simplify our calculations, assign to the unknown number *n* of HCl molecules, existing in our bilitral volume of hydrochloric acid gas, some definite numerical value, say 1000.

"This being assumed as the number of molecules in 2 litres, the number in 1 litre is of course just half, or 500; and, as we recognise that equal volumes of all gases contain equal numbers of molecules, the litre of hydrogen and the litre of chlorine, which go to the formation of our 2 litres of hydrochloric acid gas, must likewise contain 500 molecules each.

"Now, as each molecule of hydrochloric acid contains 1 atom of hydrogen joined to 1 atom of chlorine, the 1000 molecules of hydrochloric acid must, of necessity, contain 1000 atoms of hydrogen joined to 1000 atoms of chlorine—the whole number of atoms present being therefore 2000.

"But we have just seen that one litre of hydrogen and one litre of chlorine contain, not 1000 molecules each of the respective bodies, but only 500.

"It follows clearly that 500 *molecules* of hydrogen and 500 *molecules* of chlorine have supplied respectively twice as many *atoms* of those constituent bodies; each contributing its 1000 atoms to the aggregate number of 2000 atoms, existing in the 1000 HCl molecules, contained in our 2 litres of hydrochloric acid gas.

"If 500 molecules of an elementary gas supply 1000 atoms it is plain that each molecule supplies 2 atoms; and thus we clearly perceive that the molecule of the compound gas under review, and the molecules of each of its elementary constituents, are all formed on the same type—that type being the first of our quadruple series, viz., the hydrochloric acid or *diatomic* type.

"This is a remarkable and striking, yet strictly logical deduction. It completes a chain of reasonings which, if correct, justify the conception that simple as well as compound gases are complex as to their molecular structure; and that this structure, for all the permanent elementary gases, is of the diatomic type."

THE CHEMISTRY OF METEORITES.

BY W. WARINGTON SMYTH, M.A., F.R.S.

M. Daubrée, already so distinguished for his researches on metamorphism, has recently published the results of his Synthetical Experiments on Meteorites, and has thus brought before us, from an entirely different point of view, an inquiry into the nature and origin of the silicated magnesian rocks and minerals.

M. Daubrée first describes his experiments on *the imitation of the meteoric irons.* The most characteristic feature of these masses is the crystalline pattern (Widmanstätten's figures) which is brought to view on a polished surface by the action of an acid. Simple fusion of the meteorite of Caille (Var) in a *brasque* of alumina (to avoid the contact of carbon, which would have combined with the iron), was insufficient to reproduce the appearance, although the resulting substance was certainly crystalline. Further experiments, in which soft iron was associated with some of the other substances that commonly accompany meteoric iron, such as nickel and protosulphide of iron and silicon, yielded a highly crystalline result, but not yet of the true character. If, however, to the soft iron was added phosphide of iron, in the proportion of from two to five or ten per cent., and, still better, if there was introduced at the same time nickel, and if a mass of as much as two kilogrammes in weight was operated on, there appeared, when the cooled lump was polished and etched, in the midst of dendritic patterns of great regularity, lines of a brilliant material dispersed in a reticulated form.

A third mode of attempting the imitation was that of melting down certain terrestrial rock-substances, as peridote, lherzolite[*], hypersthene, basalts, and melaphyres. By this means specimens of iron were obtained which, both in composition and structure, bore strong resemblance to many of the siderolites. Especially was this notable in the metal obtained from the lherzolite of Prades (Eastern Pyrenees). These artificial irons were then found, like the natural meteoric ones, to contain nickel, chromium, and phosphide of iron, the latter in long needles recalling the appearance of the natural patterns.

Imitation of the Meteoric Stones.—Contrary to what might have been expected from the appearance of the black vitrified crust on the surface, the substance produced by the melting down of meteorites obtained from above thirty different falls, was in every case highly crystalline. Those of the common type present a group of metallic granules, disseminated in a stony mixture of peridote ($\dot{M}g_2\ddot{S}i$) and enstatite ($\dot{M}g\ddot{S}i$), the former generally on the surface as a thin crystalline pellicle, the latter in the interior as long acicular crystals. A notable contrast was yielded by the aluminous meteorites, such as those of Juvinas, Jonzac, and Stannern, which produced, instead of crystalline, a vitreous mass.

But perhaps the more remarkable results were those obtained synthetically by melting down pieces of rock characterised by the minerals peridote and enstatite. For this purpose peridote (olivine), from the basalt of Langeac (Haute Loire), and lherzolite, from Vicdessos and Prades, were fused in earthern crucibles. They melted easily and yielded crystalline substances, the latter especially closely resembling the original rock. The proportion of enstatite (the bisilicate of magnesia) was found to be increased by the addition of silica.

When similar mineral substances were melted in presence of a reducing agent, the iron (which in the other case remained combined in the silicate) segregated itself in grains of various sizes, separable by the magnet. Thus a perfect analogy was established between the above rocks and the meteorites, as well in their stony minerals as in the iron, which always contained nickel.

Furthermore, some remarkable characters in the structure of the stony meteorites were found to have been imitated, especially the delicate parallel lines attributable to cleavage, which are visible when a thin slice is examined under the microscope, and the globular structure where the little spherules are sometimes smooth at the surface, at others drusy, or roughened with the points of minute projecting crystals, like the meteorite of Sigena, November 17, 1773.

When hydrogen was employed as the reducing agent, the results were very similar, and the reaction would take place at a temperature not exceeding red heat.

Again, another method of imitation, the reverse of the foregoing, was by oxidation. From silicide of iron, heated in a *brasque* of magnesia by the gas blowpipe, a substance was obtained extremely similar to the common type of meteorite. The iron was separated partly as native iron, partly as a silicate, forming peridote, some of it in the crystallised state. Further details of resemblance were attained by heating a mixture of silica, magnesia, and nickeliferous iron, phosphide and sulphide of iron. The stony gangue of the melted product was found to be free from the latter three substances; and instead of the simple phosphide introduced in the experiment, there was observable the triple phosphide of iron, nickel, and magnesium, first noticed by Berzelius in meteoric irons.

The preceding experiments suggest some important deductions on the condition of the planetary matter from which the meteorites have been diverted to our own globe. M. Daubrée makes no attempt to enter the lists with Von Haidinger[*], Baron Reichenbach, Prof. Lawrence Smith, and others, on the questions attending the entry of these bodies into our atmosphere, and the circumstances of their fall; but, considering that their surface alone is modified by these conditions, he infers that their interior mass remains the same as when it was wandering in space, and may to a great extent be taken as a sample of the material of the planetary bodies of which they are the fragments.

Seeing how nearly the composition and structure of the meteorites are reproduced by the two methods of

---

[*] Lherzolite (so called from Lherz, in the Pyrenees) is a rock composed of peridote, enstatite, and pyroxene (augite).

[*] See Haidinger, *Phil. Mag.* November and December, 1861.

experiment, M. Daubrée refers by their aid to the original mode of formation of the bodies from which these meteorites come.

If they were produced from silicated minerals by reduction, in which carbon was the reducing agent, it may be objected that the iron could scarcely have remained in the metallic state; and if hydrogen be supposed to have been the reducing agent, water ought to have been formed at the surface, whence it appears more simple and reasonable to recur to the idea of an oxidising process. Allow that silicon and the metals existed at one time in the meteorites, not combined with oxygen as they now mostly are, and this by reason either of too high a temperature to allow them to remain in combination, or of too great a separation of their particles, then, as soon as, by their cooling down or by their condensation, the oxygen was able to act upon the other elements, it would at once combine freely with those for which it had most affinity, and if not sufficient in quantity to oxidise the whole, or not enabled to act long enough, would leave a metallic residue. In fact there would be produced the silicate of magnesia and iron, peridote or olivine, and granular portions of nickeliferous iron and of sulphides and phosphides of iron. These views, whilst applicable to a large proportion of the meteoric bodies, would require modifications for those rarer varieties which consist essentially of pyroxene and anorthite. Whilst the magnesian silicates crystallise so readily after simple fusion, these latter substances would only melt to vitreous and amorphous masses, and in order to become crystalline would have needed the presence of water.—*Address to the Geological Society. Anniversary meeting*, 1867.

ON THE PRACTICAL LOSSES IN THE BLEACHING-POWDER MANUFACTURE.

BY C. R. A. WRIGHT, B.SC., F.C.S.

The difference between the amounts of bleaching powder of a given strength obtainable theoretically and practically from a given quantity of manganese ore, depend mainly on three circumstances, viz:—

1. Incomplete decomposition of all MnO_2 used.
2. Loss of chlorine by leakage from the generators, conducting pipes, and powder-chambers, and non-absorption by the slacked lime of all the chlorine supplied to it.
3. Deterioration of the powder made, either by loss of hypochlorous acid from the action of the atmospheric CO_2, or by conversion of hypochlorite into chlorate and chloride, or other compounds deficient in bleaching-power.

In practical working, it is very difficult to obtain a good estimate of the several amounts of loss experienced from these three causes; the total loss, however, is readily calculable when the weights of manganese ore and bleaching-powder used and made, and the average percentage of MnO_2, and available Cl contained therein, are respectively known. Thus, taking 55 and 35·5 as the respective equivalents of manganese and chlorine, 100 parts of manganese ore containing M per cent. of "available binoxide" should yield $\frac{71}{87} \times$ M parts of chlorine, and consequently should theoretically give $81{\cdot}61 \times \frac{m}{n}$ parts of bleaching-powder containing n per cent. of "available chlorine."

The following results were obtained as the average losses, in different periods extending over several months each, in a works manufacturing upwards of 70 tons of bleaching-powder weekly.

Average per cent. of available chlorine in the powder packed in casks ready for sale.	Average per cent. of available MnO_2 in the manganese ore used.	Practical yield: the theoretical being taken as 100.
35·00	64·00	76·8
35·35	66·50	75·7
35·19	66·70	72·8

On the whole, therefore, the total average loss is just 25 per cent. of the theoretical yield.

These results were obtained by the "Lancashire" mode of working; *i. e.* where the chlorine generators, or stills, are formed of flags from 4 to 7 inches thick, jointed together and made tight by a composition of fire-clay and tar, known technically as "Barytes." The average amount of powder manufactured per square foot of surface on the floor of the chambers was 13·5 lbs. weekly; while the ratio of the cubic contents of the stills to that of the chambers was about 8·1 to 100. Out of a 100 parts of chlorine contained in the salt decomposed, upwards of 80 were obtained as yellow muratic acid of 25° Twaddell (25 per cent. of HCl), and 15 in the shape of bleaching-powder.

It was found that the average percentage of chlorine found in samples taken from the floor of the chambers immediately they were opened was about 1 per cent. more than the average in the same powder when packed in casks ready for sale, and, contrary to expectation, that this difference was almost exactly the same in hot weather as in cold; the numbers obtained being:—

	Summer months.	Winter months.
Average of samples from chambers........	35·09	36·71
" " casks	34·98	35·71
Difference	1·11	1·00

This difference therefore amounts to $\frac{1{\cdot}05}{36{\cdot}4}$ or three parts in 100 on the average for a whole year, and probably represents the atmospheric action on the powder during the processes of packing in casks, etc. Bleaching-powder manufactured in hot weather was frequently found to contain perceptible quantities of chlorate; samples kept in a warm place in sealed bottles were found at the end of some weeks to contain several per cents of chlorate: it was, however, found impracticable to determine the average amount of chlorate found in the process of manufacture.

The physical character of the sifted and slacked lime employed was found to have a great influence on the rapidity of absorption of the chlorine, and on the quality of the powder produced. It was noticed generally that those quicklimes technically called "Fat," (*i. e.*, which slack, rapidly falling to a fine flowery powder,) gave always the most satisfactory results; whilst poorer limes which did not slack so quickly, and yielded a gritty powder after slacking, absorbed chlorine much less rapidly, and gave a bleaching powder deteriorating much more rapidly on keeping. Samples of these two kinds of bleaching powder kept in a warm place under the same conditions acted thus: less chlorate was found in the first kind (Fat lime), and no gas was evolved; more chlorate was found in the second kind, and frequently gases were generated, rupturing the sealed vessel containing the same. On making careful analyses of the limes from which these powders were made, scarcely the slightest chemical difference was detectable, all containing but a few tenths per cent. of combined silica, and scarcely any other impurity; physically, however, the former kind attracted moisture from the air very much more rapidly than the other.

By way of comparison with the foregoing numbers, the following calculations are given, based on data given in "Richardson and Watts's Technological Dictionary," vol. i. part. iii. p. 379:—

(1.) 26 cwt. of 64 per cent. manganese yield 24—26 cwt. of powder of 35—38 per cent. of chlorine; averaging, therefore, 25 cwt. at 36·5 per cent. Hence the practical average yield is 61·2 per cent. of the theoretical amount.

(2.) 2240 parts of salt give 2753 of acid of 28 per cent. HCl, and with 448 parts of manganese ore at 60 per cent., yield 416 of bleaching powder at 39 per cent. Assuming the salt to contain, as is probable, 93 per cent. of NaCl, out of 100 parts of chlorine contained in the salt, 59·3 are obtained as strong acid, and 12·8 as bleaching powder; the practical yield of powder from manganese being 74·0 per cent. of the theoretical quantity.

Chemical Laboratory, St. Thomas's Hospital.

ON SOME USEFUL APPLICATIONS OF CHLORIDE OF CALCIUM.

BY J. HARGREAVES.

THE utilisation of waste products has within the present century become an object of great importance, and the results such, for instance, as obtaining ammonia, benzol, aniline and its derivatives, etc., from coal-tar; garancin from madder waste, acetic and oxalic acids from sawdust and other ligneous materials, ammonia, animal charcoal, and manure from bones, have been sufficiently profitable to encourage further attempts in the same direction. The writer hopes that the following may result in directing attention to some of the means of utilising another waste product.

There is produced in the manufacture of soda by Leblanc's process a larger quantity of hydrochloric acid than can be utilised. The principal use to which it is applied is for the production of chlorine in the manufacture of bleaching powder, but this uses up only a comparatively small proportion of the total production; and many alkali manufacturers throw away nearly all the hydrochloric acid made by them, causing a great amount of mischief in the streams into which the acid is run, in many instances completely ruining them as fishing streams, while the conduct of the luckless manufacturer who can find no better use for his acid, is commented upon by anglers and the lovers of fish diet, in language more remarkable for force than refinement: the former find their sport ruined, and the latter their favourite article of food destroyed.

This acid instead of being thrown to waste can be used to produce chloride of calcium by filling the condensing towers with limestone instead of coke, adding more stone as it is dissolved away by the acid, thus supplying a quantity of chloride of calcium almost unlimited. Or the chloride of calcium may be produced by the reaction of hydrochloric acid, on alkali waste in suitable apparatus, and using the sulphuretted hydrogen given off, in the manufacture of sulphuric acid. There are practical difficulties in the way of adopting this mode of making chloride of calcium, but are they impossibilities? The chief difficulties are that unless great care is taken there is an escape of sulphuretted hydrogen which is not only very disagreeable but is liable to explode when mixed with the atmosphere. Great care is also required when burning sulphuretted hydrogen, for if the supply of air is deficient, sulphur is sublimed and passed into the vitriol chambers unburnt, and if the supply of air is for a short time cut off, sulphuretted hydrogen is liable to get into the chamber and cause an explosion on the admission of an excess of air afterwards. In fact, making sulphuric acid by the use of sulphuretted hydrogen has after many trials by various inventors been found to be one of those matters which become dangerous and impracticable in the hands of ignorant workmen (another illustration of how the ignorance of a population restricts the sources of wealth in a nation).

Another cheap source of chloride of calcium is to be looked for in the bye products from several other processes for the recovery of sulphur from alkali waste, such, for instance, as that of M. Mond, a description of which lately appeared in the CHEMICAL NEWS. The chloride of calcium has in this case the advantage of being free from arsenic, the arsenic being precipitated along with the sulphur as tersulphide. Another ready source of chloride of calcium exists in the bicarbonate of soda manufacture; the chloride is obtained when limestone is acted upon by hydrochloric acid for the production of carbonic acid.

The chloride of calcium by whatever means obtained, should, if it has to be carried to a distance, be boiled to dryness in a reverberatory furnace, and the heat urged till the chloride is in a state of igneous fusion, then drawn into suitable moulds, and when cold it is in a fit condition for packing and transport. It should be packed so as to be protected from the air, on account of its deliquescence.

One of the most prominent reasons why the collection of manure by sedimentary deposition from sewage is not practised, is, that the greater portion of the manurial ingredients, and among them a great proportion of that most important one, phosphoric acid, are held in solution, while the least valuable are contained in the sediment. Chloride of calcium added to town sewage causes the precipitation of phosphoric acid from the soluble phosphates. The compounds of nitrogen are not, however, precipitated except in a very small proportion, and are therefore lost, when only the sedimentary portion of the sewage is used, but this is of little importance compared with that of the loss of the phosphates, as the atmosphere will in time supply to plants sufficient hydrogen, carbon, oxygen, and nitrogen, though of course the latter elements will not be so rapidly assimilated by the plants, as would be the case were they supplied with the manure; but the mineral elements if once exhausted can only be re-supplied by artificial means. Chloride of calcium added in excess to sewage also exerts antifermentative and antiseptic properties, retarding the decomposition of the organic portion; and when fermentation does occur, the evolution of the nauseous and poisonous sulphide of ammonium produced by the decomposition of organic compounds of sulphur and nitrogen, is prevented, by production of chloride of ammonium and sulphide of calcium,* $NH_4S + CaCl = NH_4Cl + CaS$. And when

---

* This and the succeeding reactions are inverted when the materials are heated.

carbonate of ammonia is produced by the decomposition of compounds of nitrogen, from which sulphur is absent, or fixed by other combinations, the evolution of ammonia is prevented by the formation of the less volatile chloride of ammonium $NH_4OCO_2 + CaCl = NH_4Cl + CaO\,CO_2$. The addition of the chloride is an effectual preventive of the evolution of compounds of ammonia from stable manure and from cesspools. These properties make chloride of calcium an effective agent in preventing the waste of phosphoric, and, in some cases, ammoniacal compounds, and are well worthy the attention of agricultural and sanitary reformers.

When esparto or other vegetable fibres are used in the manufacture of paper, a solution of caustic soda is employed for dissolving out the resinous and gummy portion of the vegetable from the fibre. The waste lye produced by the operation is allowed to run off in the form of a deep brown-coloured liquid, and consists of extractive matter, and resinous and fatty substances, combined with soda in the form of soap, together with carbonate of soda, caustic soda, and notable quantities of phosphate of soda. All these soda compounds are decomposed by chloride of calcium, causing the formation of corresponding lime compounds and chloride of sodium. The lime compounds being insoluble, are precipitated, carrying with them a large proportion of organic extractive matter, leaving the water with comparatively little colour, and by converting the soda present into common salt, depriving it of many of those noxious qualities which cause paper works to be regarded with such disapprobation when situated on the banks of fishing streams. The precipitate contains all the elements of an excellent manure; its principal disadvantage is owing to the great quantity of water adhering to it, which renders it difficult to remove, and dilutes the manure; but a little practical experience will remove this objection—perhaps spreading it in shallow layers to dry and drain might make it sufficiently concentrated. The chloride of calcium has, in practice, to be used in excess of the quantity theoretically necessary; that excess, however, does not perceptibly injure the water for supporting life in aquatic plants and animals.

On the one hand, the streams of one part of the country are polluted with a powerful alkali, and in another with a corrosive acid; in both instances the streams are unfitted for supporting animal life. In many cases rivers once abounding in salmon, trout, and other valuable edible fish, are now deserted in consequence of these pollutions. All that is required to put an end to this state of things is to use the one to neutralise the other, and produce a harmless neutral salt, and, at the same time, prevent our manurial wealth leaving us by being carried to the sea.

The writer has not at hand the means for forming a correct estimate of the quantity of chloride of calcium that might practically be obtained; but it is evident to any one having any acquaintance with the immense manufactories of soda on the Tyne, the Clyde, and the Mersey, that many thousands of tons of chloride of calcium per annum may be obtained, and the precipitation that of phosphate of lime from sewage, and the use of that precipitate as manure, would go far to supplement or supersede the phosphates imported in the form of guano and bones. All the materials used in its manufacture are cheap and abundant, in some instances costing less than nothing, inasmuch as some of them have at present to be removed out of the way at great expense of carriage and space in which to deposit them.

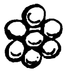
Appleton-Widnes, Aug. 19, 1867.

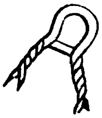
NOTES ON CRYSTALS DEPOSITED FROM THE BRAIN.

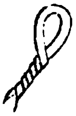
BY S. W. MOORE.

In the month of June this year (1867), Mr. Stuart, curator of the Museum, St. Thomas's Hospital, called my attention to the fact that he had noticed in some of the brain preparations a deposit of crystals which appeared to him to present a very beautiful and unusual appearance; he thought, perhaps, that I might like to examine them chemically, which I have done, thinking the results may lead to facts which will ultimately throw some light on the now very imperfectly understood compounds of the brain.

On inspecting a jar containing the deposit, there was found a very thick layer of crystals at the bottom, which upon further inspection were seen to have the form of rhombic plates; over these, however, there was a layer of what might have been mistaken for mucous or brain matter, but on examination with the microscope they presented a very beautiful appearance, two or three distinct forms being apparent, viz.—*a*, small stars, formed of globular bodies (of which there were seven, six aggregated round one), a little smaller than the male human blood corpuscle. *β*, resembling two pieces of tape, one in a semicircle, the other stretched across its diameter, the ends on both sides being twisted. *γ*. This form was one piece only, its ends being brought round upon one another and twisted.







These strange forms suggested the idea that some albuminous principle might probably have united itself with a crystalline substance, and have caused these structures to become manifest in the attempt to crystallize; they gave under the influence of polarized light a distinct cross, and what seems to confirm the supposition of their being a colloid is that upon testing nitrogen was developed. They are saponified by KHO, and dissolved by hot absolute alcohol, and separate out on cooling in a granular form, and are of course insoluble in water.

On presenting the various tests to the crystals which were so densely crowded at the bottom of the vessel, some very interesting data were collected, agreeing with the tests for no other hitherto mentioned brain compound.

In appearance the crystals were waxy, they were tasteless and insoluble in water; on ignition they burned away with a bright smoky flame, leaving no residue whatever. The tests for N, P, and S, were carefully applied, but with no result; the substance was precipitable from its ethereal solution by alcohol; its melting-point was 103° C., and on combustion it gave the following percentage:—

Carbon	43·79	
Hydrogen	8·09	
Oxygen	48·12	by difference
	100·00	

From this an empirical formula may be calculated, having the following constitution, $C_7H_{16}O_6$, or $C_{12}H_{26}O_{10}$, the latter perhaps giving a calculated result nearer the found one, viz.,—

Carbon	43·64
Hydrogen	7·88
Oxygen	48·48
	100·00

From the results obtained above we may safely conclude that the substance is not cholesterine, its high percentage of oxygen, and its low melting-point, excluding it from that supposition. It is equally impossible that it should be cerebric acid, because it is perfectly neutral and contains no nitrogen, the absence of phosphorus proves it cannot be oleophosphoric acid.

I hope to obtain some more of the substance, when further experiments will be made, from which I shall doubtless obtain something of a more definite nature, and be enabled to give it a rational formula, it appearing to have been up to the present time unnoticed.

On exposing to the air the spirits from which the crystals had been taken, a fresh crop formed; these, however, were only crystalline plates of cholesterine.

AN IMPORTANT ADJUNCT TO THE INDUCTION COIL.

BY HENRY MORTON, PH.D.

The arrangements I am about to describe have proved of great value to me, and will, I presume, be of like use to others who may have need of similar lecture illustrations.

Take eight plates of glass, about 11 inches by 14 inches, and attach to both sides of each plate sheets of tinfoil 7 inches by 10 inches in size, with rounded corners. Set these plates upright in a box (provided with grooves for the purpose) about 1 and a half inches apart; then, rolling up some balls of paper large enough to fit between the plates, and wrapping a strip of tinfoil around each ball, thrust them between the plates, and, lastly, make an outside pole to the terminal sheets of foil by means of wires enclosed in glass tubes passed through the side or top of the box. It is evident that we have here a compact form of Leyden battery arranged for "cascade." With the ordinary electrical machine such an arrangement would be worthless from its want of insulation. With the induction coil, however, which developes an entire charge in an instant, it becomes of great value in a certain class of experiments, because it gives us at once the concentrated charge peculiar to the Leyden battery, combined with a spark length which is otherwise lost. (This property of long spark in the "cascade" arrangement of jars is well known.)

If such an apparatus as we have just described be connected with the secondary poles of an induction coil, and other wires are then led off (with a break in the circuit, however, of ¼ to ¾ inches) to some piece of apparatus for the illustration of electric discharge in vacuo, such as Gassiot's cascade (especially with a canary goblet), the Aurora tube, an electric egg of canary glass, etc. (but not a Geissler tube), the brightness of the illumination and volume of the discharge will be immensely increased. Thus a goblet invisible at 30 feet when the unaided coil is used, becomes *brilliant* at 50 feet with this attachment. I have used two coils with the above apparatus, both made by Mr. E. S. Ritchie, of Boston, one (which is my own property) yielding a spark of 8 inches, the other (also in my hands, as it belongs to the Physical Cabinet of the University of Pennsylvania) which gives, in its present mounting, sparks of 16 inches, but is capable of yielding sparks two feet in length. Such sparks were, in fact, obtained from it by Mr. Ritchie during its manufacture; but, in mounting it, the poles have been secured at a maximum distance of 16 inches to provide against accident, such a length being abundantly sufficient for use. How the above battery would work with smaller coils I cannot say. Geissler tubes, unless of very large area, are not benefited in appearance by this arrangement; because, as I believe, the coil unaided can supply all the electricity they are capable of transmitting, and this excessive charge only tends to develope inductive resistances in the glass tubes themselves, which resistances this *momentary* current is the least fitted to overcome.

Allow me to mention another little practical detail in this connection. It is generally assumed that the induction coil is unfit for the exhibition of those experiments of attraction and repulsion which especially characterise statical electricity. A great number, however, may be very satisfactorily exhibited by charging Leyden jars and using them as the sources of electricity. Thus, connect a chime of bells with the knob of a large jar, connect the outer coating with the earth and with the negative pole of the coil; then bring the positive pole within striking distance of the knob, and charge by a few sparks. The electrical flyer, orrery, sportsman and birds may be successfully operated in this way, even in summer weather.

Probably, however, the coil should not be of less than 6 inches spark length.

University of Penna., Philadelphia.

ON THE SO-CALLED "INACTIVE" CONDITION OF SOLIDS.

BY CHARLES TOMLINSON, F.R.S.

In the Chemical News for the 2nd of August (*Amer. Reprint, Oct.* 1867, page 162) is given a notice of my paper on the above subject, in which I endeavour to prove that the action of solids in disengaging gases from their solutions, or in inducing crystallisation in saline solutions, is simply a question of adhesion depending on the state of purity of the surface of the solid. I have since endeavoured to express my theory in such general terms as to embrace a larger number of phenomena, which indeed seem to increase the more it is examined.

My theory, as it now stands, is as follows:—

Any supersaturated solution of gas, with its upper surface freely exposed to the air, is always giving off that gas, either with effervescence, or silently and imperceptibly. It does so because the excess of gas has only a slight adhesion for the liquid, and the air is virtually a vacuum for it, the only difference being, that it would pass off into a real vacuum suddenly and instantaneously. The remaining surface of the liquid, or that confined by the sides of the vessel, is in exactly the same state, subject however to two conditions—(1) the purity of their surface, and (2) the pressure exerted by them (virtually) on the liquid.

(1.) Suppose the vessel to be chemically clean. No gas will be disengaged, and no bubbles will form on the sides, because the adhesion between the sides and the liquid is perfect. Hence the sides may be considered, *pro râta*, as merely a continuation of the liquid itself, and no bubbles will form there any more than in the central parts of the liquid. But suppose the sides to be dirty, adhesion is diminished *or* annulled; and therefore the surface of the liquid next to such sides is virtually as free as its upper surface. (2.) Hence bubbles will form here, just as they form on the upper surface; but in the latter case they do not appear as bubbles (except in effervescence) because there is no pressure. The sides do exert pressure, and therefore bubbles are formed. Now it does not at all matter whether there be air or not between the sides and the liquid: there may probably be a vacuum or any other gas. The result will be the same. Hence it is futile to talk of the air as disengaging bubbles, as in M. Gernez's theory; it is really want of adhesion. Now to apply this to the case of the so-called "inactive" glass rod. A rod, a coin, a piece of flint, etc., placed in the liquid, does nothing more than form new sides, as it were, to the vessel, and its effect is merely that of the sides. If chemically clean, the rod, etc., will form no bubbles round it, and it is called "inactive" because its adhesion is perfect. If dirty, the surface of liquid in contact with it will be as free, or almost so, as the upper surface.

The same theory applies equally well to the action of *nuclei* in inducing crystallisation. It also applies to the common theory of ebullition, and the action of the vessel in raising or lowering the boiling-point under the same pressure. Writers down to our own day state that water boils at about 105° C. in a glass vessel, and at 100° in a metal vessel; at a lower temperature in vessels whose internal surfaces are rough than in smooth ones; that *bumping* is produced when the liquid has comparatively little adhesion to air; and soon I think it can be proved that these and other phenomena which figure in our text-books as remarkable facts, can be explained with reference to the same law of adhesion, and have nothing to do with the air except indirectly.

King's College, London, Aug. 31, 1867.

REVISION OF THE MINERAL PHOSPHATES.

BY A. H. CHURCH, M.A.,

PROFESSOR OF CHEMISTRY, R.A. COLLEGE, CIRENCESTER.

(Continued from vol. XII., p. 183, Eng. Ed. CHEM. NEWS.)

No. VI. OSTEOLITE.

A STATEMENT appears in some chemical works to the effect that osteolite, a white and compact mineral not unlike fine lithographic stone, is really pure tricalcic diphosphate $Ca''_3 2PO_4$. All the analyses, however, of the substance which have been published, point to a very different conclusion; and, in fact, a pure native tricalcic diphosphate is still unknown. My analyses of specimens of osteolite from various localities serve to confirm the notion that this so-called species is merely an apatite more or less altered by the substitution of calcic carbonate for the chloride or fluoride.

One of my specimens was from Eichen, Wetterhau. It was white, hard, and tough, showed slight signs of being stratified, and had a density of about 2·86. The following are the analytical results:—

35·46 grains osteolite gave........	·83 grain	HO
" " "	30·97 "	$Ca''_3 2PO_4$
" " "	4·26 "	$Ca''CO_3$
55·32 " "	1·39 "	CO_2

From these results we find that more lime was present in the mineral than sufficed to saturate the phosphoric and carbonic acids. Qualitative tests revealed the presence of much fluorine. If the remainder of the calcium be calculated as if in union with fluorine, the following satisfactory percentages are shown:—

$Ca''_3 2\ PO$	87·25
$CaCO_3$...........................	5·70
CaF_2	4·92

Osteolite, therefore, cannot rank as a distinct species: it is a more or less altered apatite.

ON THE REFRACTION EQUIVALENTS OF SALTS IN SOLUTION.*

BY J. H. GLADSTONE, F.R.S.

THE British Association has already more than once heard of "refraction-equivalents," but for many chemists the term may still require definition. It is well known that every body has the power of bending a ray of transmitted light, and that this power may be expressed by a number, termed the "refractive index." Now this "refractive index," *minus* unity, divided by the density of the body, is termed its "specific refractive energy,"—a property of great importance, and one that accompanies the body, notwithstanding great physical or chemical changes; for instance, to quote words formerly used, as a rule, when a gas, liquid, or solid dissolves in water, it preserves its specific refractive energy."† For many purposes it is convenient to multiply this number by the atomic weight of the substance, and that is termed its "refraction-equivalent."

Now it is not difficult to arrive at the refraction-equivalent of a salt in solution. Let a weight of it, answering to its chemical equivalent, be dissolved in a certain number of equivalents of water; the refraction-equivalent of the whole solution will consist of the refraction-equivalent of the salt, *plus* so many times the refraction-equivalent of water; and as this number is known, we have only to subtract it from the whole to obtain the refraction-equivalent desired.

It occurred to me that if a series of salts in solution were thus examined, I might arrive at numbers from which many interesting facts might be deduced, and especially that it might afford data for determining the refraction-equivalents of all the metals, and of those substances with which these metals will combine to form soluble salts.

As the determinations are matters of great delicacy, especially when the solutions are weak, I am having a superior apparatus made by Mr. Browning for the purpose; but some preliminary observations have been made with the old apparatus of Baden Powell, and these perfectly confirm my expectations, and induce me to undertake a careful examination of the whole subject.

In the first place I prepared solutions of iodides,

---

* Read before the British Association, in Section B.

† *Journ. Chemical Society*, May, 1863.

bromides, and chlorides. The metallic iodides gave refraction-equivalents ranging from 30·5 to 35·3; the metallic bromides from 21·7 to 25·7; and the metallic chlorides from 15·1 to 18·6, the highest number in each instance being the potassium salt, the while ammonium compounds of these halogens gave numbers more than three higher. Again, it was at once evident that the dispersion-equivalent of an iodide was at least double that of a bromide, and three times that of a chloride. On comparing the salts of the same metal this difference between the halogens was still better defined, the number for the iodide almost invariably exceeding that for the bromide by a little more than ten, and that for the chloride by a little more than sixteen. It was evident, therefore, that the halogen was exerting the same influence on the rays of light with whatever metal it was combined; and that any metal, as calcium, was unchanged in its refraction-equivalent, whether it was united to chlorine, bromine, or iodine. This observation was subsequently extended to a totally different class of salt, the sulphates, which give numbers always about one less than those given by the chlorides.

It may be asked—What numbers do you deduce from these results as to the refraction-equivalents of the metals? Unfortunately I am not in a position to reply with certainty. If we knew the refraction-equivalents of chlorine, bromine, or iodine, it would be easy; but the numbers previously deduced for them from organic compounds evidently require some rectification before they can be applied to this purpose. I hoped to arrive at the matter from the refraction-equivalents of the hydracids in solution, as the number for hydrogen is known to be 1·3; but I obtained such high numbers for hydriodic, hydrobromic, and hydrochloric acids, that I am disposed to think hydrogen in these compounds must exert a far greater refractive influence on the rays of light than when alone, or combined with carbon or oxygen.

In any case the refraction-equivalents of the metals examined in solution are very low as compared with the known refraction-equivalents of non-metallic bodies, except those that have very small atomic weights. They present themselves in about the following order, commencing with the lowest:—Magnesium; lithium; sodium; zinc; calcium; manganese; cadmium; copper; strontium; iron (ferricum); barium; potassium; ammonium.

ON THE COMMERCIAL ANALYSIS OF SOME OF THE PRODUCTS AND MATERIALS OF THE ALKALI MANUFACTURE, Etc.

BY C. R. A. WRIGHT, B.S.C., F.C.S.

(I.) **Salt-cake.**—Ordinary salt-cake is valued according to the percentage of "Available sulphate of soda" contained; *i.e.*, the percentage of Na_2SO_4 existing mainly as such, and partly as $NaHSO_4$. The mode of estimation of the available sulphate usually pursued is the following:—

1. The NaCl is determined volumetrically by a standard silver solution.

2. The quantity of a standard alkaline solution required to render a known weight of salt-cake exactly neutral to test papers is determined, and the result, sometimes calculated as SO_3 sometimes, as SO_4H_2, called "free acid."

3. The difference between the sum of the two previous determinations and 100 is assumed to be "available sulphate of soda."

By this mode of proceeding errors of one to three or more per cent. are introduced; ordinary salt-cake containing, in addition to Na_2SO_4, $NaHSO_4$, and NaCl, perceptible quantities of $PbSO_4$, $Fe_2\ (SO_4)_3$, Fe_2O_3, $CaSO_4$, $MgSO_4$, moisture, and particles of sand, brick, etc., derived from the furnace during the manufacturing processes. Where a greater degree of accuracy is desirable, a known weight of salt-cake may be treated with water, ammonia and ammonium oxalate added to the unfiltered solution, and the precipitated Fe_2O_3 and $CaCO_3$, with the insoluble matters, weighed after ignition: by moistening the ignited precipitate with pure SO_4H_2, and igniting again, the $CaCO_3$ is converted into $CaSO_4$, and then the weight of the mixed substances indicates all the "impurities" present in the salt-cake, with the exception of the $MgSO_4$, which rarely amounts to more than traces, and the moisture, which is occasionally a very perceptible quantity, especially in samples that have been made some length of time.

The amount of ferric sulphate present depends on the degree of heat to which the salt-cake has been subjected during manufacture. In highly roasted samples, cold water yields a solution containing no iron whatever, all the iron present in the salt-cake consequently existing as Fe_2O_3; specimens of under-roasted salt-cake, on the other hand, when treated with cold water, leave only fragments of brick, $CaSO_4$, etc., undissolved, all the iron existing as $Fe_2(SO_4)_3$. In ordinary salt-cake, however, there is so little ferric sulphate, that no perceptible error is committed in assuming that all iron present exists as Fe_2O_3, and all the "free acid" as $NaHSO_4$. Accordingly the following methods have been found to give tolerably expeditiously the exact composition of such salt-cake.

(*a.*) A known weight, 5 or 10 grammes, is dried at 110°—120° C., till constant in weight; too great elevation of temperature being avoided to prevent any possible loss of HCl by reaction of the $NaHSO_4$ on the NaCl present.

(*b.*) The NaCl is determined volumetrically by a standard silver solution.

(*c.*) A solution of sodium hydrate free from carbonate, or of caustic ammonia, of known strength, is added to a known weight of salt-cake until test-papers indicate exact neutrality of the liquid; the alkaline solution used accordingly corresponds to the $Fe_2(SO_4)$, and $NaHSO_4$ together, and may therefore be safely calculated as the latter.

(*d.*) A known weight of salt-cake is boiled with an excess of a standard sodium carbonate solution, and filtered; the unneutralised alkali is then determined by a standard acid solution. The amount of alkaline solution neutralised by the salt-cake indicates the $CaSO_4$, $NaHSO_4$, and $Fe_2(SO_4)_3$ together; and hence the difference between (*c*) and (*d*) indicates the $CaSO_4$. Or the $CaSO_4$ may be determined gravimetrically by precipitation with ammonium oxalate after separation of the Fe_2O_3 by ammonia from the solution of a known weight of salt-cake in hydrochloric acid.

(*e.*) The precipitate thrown down in (*c*) may be collected and boiled with hydrochloric acid; the insoluble bricks, etc., may be weighed, and the ferric salt reduced by zinc or other reducing agent, and titrated volumetrically by permanganate or otherwise.

(*f.*) When the $PbSO_4$ is to be determined, it may be done by treating a considerable quantity, say twenty grammes, with water, and boiling the insoluble residue with strong hydrochloric acid, till the $PbSO_4$ is entirely dissolved, and from the solution PbS may be thrown down by sulphuretted hydrogen, and the lead determined in the ordinary way.

(*g*.) If $MgSO_4$ is to be determined, it may be done by dissolving a known weight, say twenty grammes, in hydrochloric acid, adding ammonia and ammonium oxalate, and precipitating the magnesia from the filtrate by a phosphate, and ultimately weighing the magnesium pyrophosphate.

(*h*.) If the preceding determinations have been carefully conducted, the difference between 100 and the sum of them may be safely taken as Na_2SO_4; if this is to be directly determined, however, it may be done either by determining the total SO_4 present by dissolving a known weight of salt-cake in hydrochloric acid, and precipitating by $BaCl_2$, and weighing the $BaSO_4$; subtracting the SO_4 contained as $CaSO_4$, $NaHSO_4$, $MgSO_4$, $PbSO_4$, the remainder being calculated as Na_2SO_4; or by adding ammonia and ammonium oxalate to the aqueous solution of a known weight, and estimation of the residue left on evaporation of the filtrate and ignition with SO_4H_2: on subtraction from this of the amounts due to $MgSO_4$,NaCl, and $NaHSO_4$, the Na_2SO_4 is directly ascertained.

The writer has obtained very concordant results by either of these plans, viz., estimation of Na_2SO_4 by difference, by determination of total SO_4 present, or by determination of total Na present. The total "available sulphate of soda" is known by adding $\frac{71}{120}$ of the $NaHSO_4$ to the amount of Na_2SO_4 found.

II.—**Black-Ash** is rarely sold as such, being generally converted into soda-ash on the spot where it is made. Commercially, the only valuable ingredient is the sodium carbonate, the amount of which is generally determined by lixiviation of a known weight of black-ash, and titration by normal test acid of the liquor obtained. In manufacturing establishments it is frequently the practice to lixiviate the ash with water at some definite temperature, considered to be about the average temperature of the lixiviating vats; the liquor so obtained is examined (*a*) for alkali, determined by test acid; (*b*) for sodium sulphate, generally estimated roughly, but with sufficient nearness for manufacturing purposes, by addition of a standard barium chloride solution to a portion of the acidulated lixiviate, till no further precipitate is thrown down; (*c*) for sulphide, estimated by passing chlorine through the alkaline lixiviate till all sulphide is destroyed; boiling with hydrochloric acid, and volumetric determination of the sulphate as before, the increased amount representing the sulphide. Prizes are frequently given to those workmen who produce black-ash containing but little sulphate, showing a nearly complete decomposition of the salt-cake employed; and occasionally prizes are given when the sulphate after oxidation is low in amount, it being supposed that this indicates that over-roasting of the black-ash has not occurred. A slight misapprehension, however, usually attends this mode of analysis; although an over-roasted black-ash will yield a perceptible quantity of sulphide when treated with nearly absolute alcohol, yet the fact of an aqueous solution containing sulphide by no means proves that the ash was over-roasted, inasmuch as on addition of water to black-ash there is always a mutual reaction between the CaS, and Na_2CO_3 contained therein; the amount of Na_2S formed therein, as the researches of M. Kolb have shown,* depends on the temperature and dilution of the liquid, and the time employed; and accordingly it is often found that the sulphide existing in the black-ash lye from the vats is very different in amount from that calculated from the laboratory analyses of the black-ash worked. The laboratory test for "sulphate after oxidation," therefore, is really useless, as it neither denotes the quality of work done by the furnace-man nor that of the black-ash lye.

The writer has shown in a recent paper (*Chem. Soc. Journ.*, xx., 407) that there is contained in ordinary black-ash a sodium compound insoluble in hot water even on long digestion, but decomposable by long continued boiling. In cases, therefore, where the total "available alkali is to be exactly determined, either this long boiling must be performed, or the total sodium present must be determined gravimetrically, and that contained as chloride and sulphate subtracted; in either case a tedious operation. The same applies in the case of the analysis of the lixiviated black-ash, or vat-waste. Ordinarily the vat-waste is examined by lixiviating or washing on a filter a known weight of waste fresh from the vats, or previously completely dried. In either case a considerable amount of calcium hydric sulphide comes into solution, and hence if the solution so obtained be immediately titrated with test-acid, more soda is indicated as present than really has been dissolved out. By passing CO_2 through the solution till H_2S is completely expelled, boiling to decompose calcium bicarbonate, and filtration from the precipitated calcium carbonate, this error is avoided. The same effect is produced by adding ammonium carbonate to the solution and boiling in a flask till no further evolution of ammoniacal gases takes place; but in either case the sodium contained in the insoluble compound, or as sulphate (found by oxidation of calcium sulphide and subsequent reaction on the sodium carbonate, especially if the waste have been previously dried), remains unestimated. When accuracy is required, therefore, a gravimetric determination of sodium is unavoidable.

In cases where an accurate analysis of the total contents of a sample of black-ash is required, the following method gives reliable results tolerably speedily. Most of the modes of determination are likewise applicable to samples of dry vat-waste:—

(*a*). A known weight is dissolved in hydrochloric acid, the insoluble coke and sand collected on a weighed filter, and the carbon subsequently burnt off.

(*b*). In the filtrate from (*a*) the SO_4 is estimated by precipitation by barium chloride and weighing the $BaSO_4$.

(*c*). A known weight is dissolved in nitric acid, and the Cl determined volumetrically by a standard silver solution.

(*d*). A known weight is treated in Mohr's CO_2 apparatus; the ammonium carbonate found precipitated by boiling with calcium chloride; the precipitate washed till the washings are neutral, dissolved in a slight excess of standard hydrochloric acid, and the excess determined by a standard alkaline solution; thus the CO_2 can be calculated.

(*e*). A known weight is fused with four times its weight of a mixture of three parts dry sodium carbonate and one of potassium nitrate (both free from sulphate). From the total sulphate thus formed, and estimated gravimetrically by barium, that existing as Na_2SO_4 is subtracted, and the remainder calculated as S.

---

* *Annales de Chemie et Physique*, June, 1866.—*Vide* Chemical News, Nos. 345—347.—[*Eng. Ed.*]

(*f*). A known weight is treated with hydrochloric acid, the filtrate oxidized by nitric acid, and the mixed $Fe_2O_3Al_2O_3$ and P_2O_5 precipitated by ammonia.

(*g*). The filtrate from (*f*) is treated with ammonium oxalate, the precipitate estimated volumetrically by permanganate, or gravimetrically as $CaCO_3$; hence the Ca known.

(*h*). A known weight is lixiviated with warm water, and in the filtrate from the insoluble matter the SiO_2 estimated by evaporation to dryness with hydrochloric acid; in the filtrate from this the Al_2O_4 combined as aluminate is determined by precipitating the alumina by ammonia.

(*i*). A known weight is cautiously treated with sulphuric acid in a capacious platinum crucible, and heated till gases cease to be evolved; the residue is treated with water, filtered and well washed, ammonia and ammonium oxalate added to the filtrate; and ultimately the total Na contained weighed as Na_2SO_4.

In calculating results from the foregoing data, the Cl found is calculated as NaCl, the SO_4 as Na_2SO_4, the SiO_2 as Na_2SiO_3, and the Al_2O_4 (soluble in water) as $Na_2Al_2O_4$, the remaining sodium is then calculated as Na_2CO_3, and the remaining CO_2 as $CaCO_3$. The sulphur is calculated as CaS, and the remaining calcium as CaO. From the total $Al_2O_3+Fe_2O_3+P_2O_5$ the alumina present as aluminate is subtracted; the coke and sand, etc., are directly determined (*a*). The difference from 100 in a carefully conducted analysis will not amount to more than a few tenths per cent., and represents cyanogen, traces of moisture, etc., and loss.

In an over-roasted ash the alkaline sulphide can only be safely estimated by digestion with nearly absolute alcohol, oxidation to sulphate by chlorine, and precipitation by barium. The Na contained as poly, or mono, sulphide, may be determined volumetrically by test acid in the alcoholic solution, and must be subtracted from that to be calculated as Na_2CO_3 as above: the S existing as poly, or mono, sulphide of sodium must be subtracted from the total sulphur found, the difference being calculated as CaS.

ON THE ECONOMISATION OF SULPHUROUS ACID IN COPPER SMELTING.*

BY PETER SPENCE, F.C.S.

It will be in the recollection of members of this Section that Lord Derby, in 1861, obtained the appointment of a committee of the House of Lords, for obtaining evidence as to the noxious vapours from chemical works, etc. That investigation, carried over many months, resulted in the passing of what is called the "Alkali Works Act," which has been so ably and successfully carried out by my friend Dr. Angus Smith.

At the same time a large amount of evidence was taken as to the emission of sulphurous acid, and arsenious acid, from the copper smelting works at Swansea, and other parts of the country; but no legislation was adopted, because, with the exception of the writer of this paper, all the witnesses testified to their being no practicable means of suppressing the nuisance without destroying the trade.

Copper smelting as now conducted appears at first sight a very crude, but is in reality a very beautiful, chemical process. The ores used are of a heterogeneous character, chiefly iron pyrites more or less impregnated with copper, and containing besides arsenides and sulphides of various other metals, with a large mixture of quartz. The first process of the copper smelter is by calcination to separate a quantity of the sulphur and as much as possible of the arsenic; for this purpose the mixed ores are exposed to a red heat, and these bodies are dissipated into the atmosphere. When calcined the ores must still retain a portion of the sulphur, varying with its richness in copper, this sulphur playing an important part in the next operation. The calcined ores are now melted down by a great heat into a fluid state, when the sulphur not dissipated unites with a portion of the iron and every trace of the copper, for which it has great affinity, and sinks to the bottom of the furnace carrying down with it any of the precious metals which may be present. The large mass of the fluid now floating at the top is silicate of iron, and is skimmed off and thrown away as slag. The *regulus* run from the bottom of the furnace contains from 20 to 35 per cent. of copper, and almost invariably 28 per cent. of sulphur. The *regulus* is again calcined to throw off the sulphur, and the subsequent processes of refining take place.

I effect the saving of sulphur by calcining in long furnaces, the bed being heated from below, air being made to travel from one end of the furnace to the other over the heated ore, the air and SO_2 being passed from the furnace directly to the lead chambers, the ore being at regular intervals made to traverse in an opposite direction, coming out calcined where the air enters. The calcination of *regulus* is exactly similar in both cases, the calcination is only carried to a certain point, 8 to 9 per cent. of sulphur being left in both the ore and regulus.

This process, carried out for several years chiefly in vitriol works, is now being successfully employed by the Goole Alum Smelting Company, on a large scale as a copper smelting process. It has been in operation there for over twelve months, and at present 150 to 200 tons of mixed ores are being smelted weekly. These ores are Cornish, Swedish, Norwegian, and Spanish.

About two months ago I sent down one of my chemical assistants to superintend during a month some large working experiments, analysing the results at every stage, so that reliable data might be got. One of these experiments I append, and as it is typical of the general operations, it may safely be taken as indicating what is being done.

	Sulphur.			
	tons.	cts.	qrs.	lbs.
10½ tons Cornish ores containing 19 per cent. sulphur 13½ " Spanish smalls " 47 " " { mixture 33·3 per cent. } =	8	0	0	0
This was calcined, the SO_2 going to the vitriol chamber. The result was 22 tons of calcined ore, containing 8 per cent. sulphur..............................	1	15	0	0
The ore when smelted gave 2 tons 15 cwt. of regulus containing 28 per cent. sulphur..............................	0	15	1	20
The loss in sulphur dissipated is therefore...	0	19	2	8
This regulus calcined, the SO_2 going to the vitriol chamber became 2 tons, 10 cwt., containing 9 per cent. of sulphur........	0	4	2	20
No more sulphur can be economised, therefore the total loss of sulphur is..........	1	4	1	0

Or as under,

Sulphur economised.................	84·8 per cent.
Sulphur lost.......................	15·4 "
Total sulphur in ore.................	100·0

* Read before the British Association, in Section B.

ON A NEW TELEGRAPHIC THERMOMETER.*

BY PROFESSOR WHEATSTONE, F.R.S.

The telegraphic thermometer which I constructed in 1843, and which is described in the report of the thirteenth meeting of the British Association, depended on the simultaneous action of two isochronous chronometer or clock movements—one at the remote station regulating the motion of a plunger in the bore of a thermometer, and the other at the near or observing station, marking, by the motion of the needle of a galvanometer, the moment at which the contact of the plunger with the mercury of the distant thermometer completed or broke the circuit. The clock movements required to be periodically wound up, and therefore the affected instrument could not be left to itself for an indefinite time. There are, however, many situations in which it might be desirable to have meteorologic indications when the instruments would not be accessible for very long periods. I have, therefore, devised a new class of telegraphic meteorometers which shall be independent of clock work, and may remain in any situation of difficult access as long as the instrument endures. This principle is applicable to all instruments which indicate by means of a revolving hand, and I have already devised its application to a Breguet's metallic thermometer, an aneroid barometer, and a hygrometer, depending on the absorption of moisture by a thin membrane. It is also applicable to a bar magnet in a fixed position, and to a variety of other indicators. The apparatus consists of two distinct instruments connected only by telegraphic wires. The first I will call the questioner (A), the second the responder (B). The questioner (A) is a rectangular box, presenting externally a circular dial face, round which are engraved the degrees both of the Fahrenheit and Centigrade thermometric scales, the former ranging from 20° below zero F. to 220° above that point, and the latter from 0° to 110° C. It shows, besides, three binding screws for the purpose of connecting the telegraphic wires, and a handle which causes the rotation of the armature of a magneto-motor in the interior. This magneto-motor is similar in its construction to that employed in my alphabetic magnetic telegraph; a soft iron armature rotating before the four poles of the magnet occasions, when the circuit is completed, alternate currents of equal intensity. The box also contains a small electro-magnet, which acts by means of mechanism similar to that employed in the indicator of the aforesaid telegraph, and causes the revolution of the index of the dial. The responder (B) is a cylindrical brass box, which presents on its upper surface a similar dial, with its thermometric scales and index; at its base three binding screws, corresponding to those of the questioner, are fixed for connecting the telegraphic wires; and it is furnished with a brass cover that it may be hermetically sealed when lowered in the sea or buried in the ground. Its interior contains three essentially distinct parts.—1. The metallic thermometer, which consists of a spiral ribbon of two dissimilar metals, with its hand capable of ranging through the extent of the circular thermometric scale of the dial;—2. A small electro-magnet, acting by means of a propelment on a disc, making as many steps in one rotation as there are half-degrees on the scale;—3. An axis to which is fixed a delicate spiral spring, which causes a pin to bear lightly against the hand of the thermometer however it may vary in position. The two instruments are connected by means of two telegraphic wires. The first proceeds from an earth plate at the near station, passes through the coil of the electro-motor in A, joins the coil of the small electro-magnet in B, and then proceeds to another earth plate at the distant station. The second wire is permanently connected with the first between the earth plate and the coil of the magneto-motor, and includes that of the electro-magnet in B, and its opposite end is brought close to the remote end of the first wire. The mechanism is so disposed that when the first wire is disconnected from its earth terminal it is brought into circuit with the second wire. By this arrangement, when the dial of A is brought to 0° and the handle turned, at the first moment the circuit is completed through the first wire, containing the coil of the electro-magnet in B, and the return earth. A disc is thereby caused to revolve in an opposite direction to the graduation of the scale until a pin, originally starting from 0°, comes into contact with the pin, pressing against the thermometer hand, and thereby completes the circuit of the second wire, and breaks the connection with the earth plate. At first only the electro-magnet in B is acted upon, but when the currents are diverted into the new channel both the electro-magnets act simultaneously. In consequence of the action of the electro-magnet in A, the hand of its dial passes over a space corresponding with that between 0° and that indicated by the thermometers and the hand of the dial ultimately accords with that of the distant thermometer. When the hand of the dial on A comes to rest the disc in B arrives at 0°, and a catch permits the spiral spring to unwind itself, and its pin flies to and presses against the thermometer-hand. It must be observed that instruments thus constructed are not capable of marking every possible gradation; but they may be made to indicate divisions of the scale of any required minuteness. It is advisable to limit the extent of the scale when more minute divisions are deemed necessary. The only circumstance that can affect the accuracy of the indications of the instrument is this—the pin pressing against the thermometric index displaces it a little, and causes it to assume a position about a degree in advance, but as this pressure is a constant one, the inconvenience is remedied by a slight corresponding shifting of the scale. In this class of instruments the indications are not spontaneously conveyed to the observer, but they must be asked for, and whenever this is done the indications will be immediately transmitted to him however frequently the question is put. The uses to which this telegraphic thermometer may be applied are, among others, the following:—The responder may be placed at the top of a high mountain and left there for any length of time, while its indications may be read at any station below. Thus, if there should be no insuperable difficulties in placing the wires, the indications of a thermometer placed at the summit of Mont Blanc may be read as often as required at Chamouni. A year's hourly observations under such circumstances would no doubt be of great value. If it be required to ascertain during a long-continued period the temperature of the earth at different depths below its surface, several responders may be permanently buried at the required depths. It will not be requisite to have separate questioners for each, as the same may be applied successively to all the different wires. The responder, made perfectly water-tight, in which there would be no difficulty, might be lowered to the bottom of the

---

* Read before the British Association, in Section A.

sea, and its indications read at any intervals during its descent. In the present mode of making marine thermometric observations, it is necessary that the thermometer should be raised whenever a fresh observation is required to be made.

ON THE ELECTRICAL RESISTANCES OF THE FIXED AND VOLATILE OILS.*

BY T. T. P. BRUCE WARREN.

The want of an acknowledged and reliable means of recognising the purity or condition of samples of oils has long been felt by pharmaceutists. No tests, or system of tests at present used are free from objection. An inspection of the optical characters of the oils, whether fixed or volatile, will be sufficient to confirm the truth of this observation.

The polariscope has at best a very limited scope of application, whilst the determination of the refractive or dispersive qualities requires such precise adjustments that the suitability either of the one or the other for the purposes of a technical test may be fairly questioned. The refractive power of the oils, both fixed and volatile, has so small a variation, even between the two extremes of the scale here given, that the difference produced on the refractive power of any oil by the addition of a small quantity of another, would be barely perceptible. The objection against the measurement of the dispersive action as a means of expressing the value of an oil, is that the determination of the differences of indices of refraction for the extreme rays is at once tedious and unreliable; the scale of dispersions offers, however, a much wider range of differences.

It is probable that the comparison of two samples of oil by the irrationalities of their dispersion is worthy of some attention. I am not aware of its being applied as a test, but the samples could stand side by side with respect to the illuminating source, and their spectra projected side by side could be easily observed and compared.

The tables here given of the dispersive powers, and the irrationalities of dispersions, are by Sir David Brewster; the refractive powers are principally by the same authority.

Table of Oils.—Arranged in order according as they contract the less refrangible, and expand the more refrangible spaces (irrationalities of dispersion).

Oil of Cassia
" Bitter Almonds
" Aniseed
" Sassafras
" Fennel
" Cloves
" Turpentine
" Carraway

Oil of Nutmeg
" Peppermint
" Castor
" Nut
" Olive
" Sweet almonds
" Alcohol

Although bromine and iodine exert on some of the essential oils chemically characteristic effects, it does not appear certain to what extent the action may be modified by the addition of small quantities of other oils; consequently the chemical phenomena, as well as a knowledge of their specific gravities, and boiling points, cannot be considered as offering any assistance to the detection of accidental or intentional impurities when existing in small quantities.

OPTICAL QUALITIES OF OILS.

The process which I have to submit to you is one which has given great satisfaction in all the experiments which I have made, and was suggested by a discovery due to M. Rousseau, quoted by De La Rive,* "that olive oil when mixed with $\frac{1}{100}$th part of its volume of oil of poppies, increased the number of vibrations of a magnetic needle in a given time, when the same was included or made to form part of a voltaic circuit." This isolated fact would be of service for the determination of the purity of olive oil, if oil of poppies were the only sophisticating ingredient.†

I thought it useful to extend the observation to the effects produced by other oils when mixed with oil of olive, and to ascertain how far the process might be applied as a test for the commercial and chemical valuation of oils generally.

For this purpose I had first to measure the resistances offered by a column of each of the oils experimented on, having in each case the same length and sectional area.

From the low resistances possessed by the volatile oils, the apparatus used by M. Becquerel for ascertain-

---

* Read before the British Association, in Section B.

* "Treatise on Electricity," translated by Walker).

† Since writing this I find the following note in "Paris's Pharmacologia" (1833), under the article "Olive Oil." "M. Rousseau has discovered the curious fact, that of all the oils, both vegetable and animal, olive oil most feebly conducts electricity. It may be stated that as a medium it acts 675 times more feebly than the others. Two drops of oil of beechmast, or of poppy seeds, poured into ten grammes of olive oil, renders the needle four times more sensible. This difference, therefore, furnished M. Rousseau, by means of his diagometer, a test for determining adulterations with precision."—(*Journal de Pharmacie*, t. ix. p. 587.)

ing the resistances of liquids might be employed,* but from the high resistances offered by the fixed oils I have designed a modification.

I must here acknowledge the obligation I am under to W. Hooper, Esq., for the use of Sir William Thomson's delicate astatic reflecting galvanometers, and a battery which possesses remarkable constancy, viz., that of Daniell's as modified by Minotte.

With such a galvanometer as used for these tests, the deflections obtained are strictly proportional to the resistances, and by means of noting the deflection produced through a constant resistance, by a standard current, it is easy to compare the results obtained at different times and under different conditions. The standard current represents a known relation to the full electro-motive power employed.

The resistances of the essential oils were determined with one cell; and I may remark that I was considerably surprised at the low resistances of the volatile oils, this being the reverse of what, judging from the composition of them generally, I was prepared to expect.

The adulterants of the volatile oils are principally turpentine and alcohol.†

Compared with any of the essential oils, turpentine has an immense resistance, whilst that of alcohol is enormously lower than any of them, except perhaps that of oil of bitter almonds, which is so low that I did not measure it.

The importance of this general fact is at once apparent, since the addition either of alcohol or turpentine in the smallest quantity is readily detected; and the quantity denoted by the variation in the deflection, either when compared with a standard of known purity, or by the resistances themselves.

The oils of lemon and bergamott, when mixed with a small proportion of turpentine, do not, however, show such marked differences as the generality of the essential oils. The addition of turpentine reduces the conducting power, or, in other words, increases the resistances to a very perceptible extent in all oils except lemon and bergamott, but in these two last cases it becomes, nevertheless, perceptible in the effects of increased resistance,—in these cases, however, a property not solely confined to turpentine aids in its detection, and consequently enlarges the scope of the application of this test. Large quantities of turpentine are instantly perceptible in increasing the resistances.

The addition of turpentine to oil of lavender is more strongly marked by this test than in any other case.

The following tables contain the averages of six tests on each oil, taken at different times. For reasons noted farther on, the same sample should not be used for a second test. The volatile oils were obtained from reliable sources, and were supplied as perfectly genuine and in mature condition. I am particularly indebted to Messrs. I. and H. Smith for the liberal manner in which they have supplied me with information respecting the samples obtained from them. I met with great difficulty in procuring samples of cotton seed oil, and although my samples are unauthenticated for condition or purity, I must acknowledge my obligation to Mr. Edward Mann, 7, Pall Mall East, for his kindness in procuring them.

* Product of 1858.

The effects produced by mixing different specimens of the same oil together are also perceptible, thus the German oils of peppermint, or foreign samples of lavender oil produce modifications in the electrolysis.

In testing the fixed oils a much higher battery power is required; this arises simply from the fact that they all possess much lower conducting powers than any of the essential oils.

For these tests thirty-two cells were used.

From this table it will be seen that the bleached oils have even a lower conducting power than the unbleached oils; and in this respect olive oil possesses a greater difference than almond oil. It is not easy to explain this.

---

* See "De la Rive's Treatise," vol. ii.

† The foreign oils are no doubt sometimes entirely substituted for the English oils, or largely diluted with them.

A singular difference exists between the Italian and the East Indian castor oils. This difference will enable one to detect a very small percentage of the one added to the other.

Cotton-seed oil and oil of poppy, as well as turpentine, are so rapidly altered in their conducting power by electrolysis, that there is not the slightest difficulty in recognising them in samples of oil.

Olive oil, when free from cotton-seed oil or oil of poppy, has its resistance increased by electrification, but if the smallest quantity of either of them exists in a sample of olive oil, it produces a contrary effect by a prolonged contact with the battery.

These results of electrolysis are alone important in determining the condition of a sample of olive oil.

I regret that I have not been able to extend these observations to commercial samples of olive oil of different qualities, and to have included a greater number of fixed oils, from the great difficulty of procuring specimens of reliability in purity or condition.

ON THE PRESENCE OF COLUMBITE IN WOLFRAM.

BY T. L. PHIPSON, PH.D., F.C.S.

I HAVE recognized the presence of columbite (niobate of iron and manganese) in a sample of wolfram from Auvergne that I have lately analyzed, which was given to me some years ago by M. Pisani. I had already remarked that wolfram from different localities sometimes contained niobic acid, sometimes tantalic acid, which can be made distinctly evident by examining before the blow-pipe the residue left when most of the iron, manganese, and tungstic acid, have been separated.

From the specimen here in question I succeeded in extracting from some twenty grammes a quantity of columbite sufficient to fill a small bottle, and to enable me to study its properties easily. The separation of this rare mineral is based upon the simple fact that wolfram is attacked by aqua-regia, whilst columbite is not. Fifteen to twenty grammes of wolfram, finely pulverized, are attacked by warm aqua-regia, and when the action has proceeded as far as possible the residue is collected, the tungstic acid separated by a solution of ammonia, and the residue again submitted to the action of aqua-regia. These operations are repeated five or six times, as long as any tungstic acid can be obtained from the residue. Finally, the latter becomes quite black, and then consists almost entirely of the mineral columbite (or niobite) mixed with some grains of transparent quartz.

After ascertaining by analysis the nature of this residue I passed it under the microscope, and saw the mineral in its ordinary aspect. It appeared in the form of angular, irregular, black fragments, more or less metallic, almost vitreous, non-magnetic, resembling up to a certain point brilliant fragments of coal; and giving all the blow-pipe reactions of columbite.

It will be remembered that M. Gustav Rose formerly ascertained that columbite and wolfram are isomorphous.

I may profit by this opportunity to state that the metal columbium, now called *niobium*, was discovered by the English chemist Hatchett in 1801, and that the metal discovered in 1802 by Ekeberg, and called *tantalum*, was really a new metal, and not the columbium of Hatchett, as Dr. Wollaston declared. The latter is niobium, a metal which has become remarkable by the persevering researches of Heinrich Rose, who has made known all its characteristic reactions. On comparing the observations of Hatchett with what is now known of tantalum and niobium, principally by the admirable analytic studies of Heinrich Rose, the fact alluded to becomes, I believe, incontestable.

London, Aug. 31, 1867.

ON A METHOD OF RECOVERING SULPHUR AND OXIDE OF MANGANESE, AS PRACTISED AT DIEUZE, NEAR NANCY, IN FRANCE.*

BY J. LOTHIAN BELL.

IN the manufacture of soda, the use of sulphur plays an important part; the office it performs being to effect, in the form of sulphuric acid, the decomposition of common salt.

The sulphate of soda obtained from this action in its turn is subjected to decomposition by exposure to heat along with carbonate of lime and coal, a process which transfers, practically, almost the whole of the sulphur to the lime, or to the metallic base of this earth, the only exception being the small portion which remains with the soda as an impurity.

This new combination of sulphur is separated from the soda salts by lixiviation, and the portions undissolved, containing the sulphides of lime and calcium, and known as soda-waste, are thrown away.

I will not dwell on the inconvenience the soda-maker is exposed to from having to provide deposit-room for such a large quantity of refuse as the mode of treatment just mentioned gives rise to, nor on the somewhat offensive nature of the soda-waste itself, rendering the alkali manufacturer's heap any thing but a desirable neighbour.

Various are the plans which have been suggested for the recovery of this, the most costly element of the soda-maker's process, but hitherto, so far as actual practice is concerned, the whole of the sulphur employed by them may be said to be still thrown aside after it has once done the duty just alluded to.

Having heard a favourable account of a method in operation, at the Chemical works of the Dieuze Company, near Nancy, by the permission of the proprietors, I visited that establishment in the month of July last, and it is to give a brief account of their process that I now have to ask the attention of this Section.

It will be convenient at this stage of the description to remind you that in most soda-works there exists another residual product, scarcely less embarrassing in its nature than that previously mentioned. The muriatic acid obtained from decomposition of common salt with sulphuric acid, along with peroxide of manganese, is employed very extensively in the manufacture of bleaching powder, a process which gives rise to the generation of a large quantity of liquid chloride of manganese mixed with chloride of iron and free hydrochloric acid. The whole of these solutions are run away into the nearest water-course in the vicinity of the different manufactories.

The process I am about to describe requires the assistance of this second equally valueless material. The operation is as follows:—The soda-waste, after being removed from the vessels in which it has been sepa-

---

* Read before the British Association, in Section B.

rated from the soda, is thrown into a tank of stonework about twenty yards long, by five in width, and six feet deep. In this vessel an intimate mixture is easily effected of the soda-waste and the metallic chlorides of the refuse from the bleaching powder process, and from which latter all the free muriatic acid has been removed in a manner to be hereafter described. Were the free acid still present, a loss of sulphur by the generation of sulphuretted hydrogen would take place, and this on all accounts it is obviously best to avoid.

A few hours suffice to convert the chlorides of manganese and of iron into sulphides, when the soluble chloride of calcium generated by the action is allowed to drain off. The solid matter remaining is cast out into a heap by the side of the tank containing it. In two or three days the heap is turned over, and in a short time a considerable elevation of temperature ensues, indicative of strong chemical action. To restrain this somewhat, the mass is kept moist, otherwise spontaneous combustion would ensue, sulphur would be wasted, and the desired results generally interfered with. During this stage of the process the metallic sulphides, under the joint action of the atmosphere and moisture, are peroxidized, and sulphur is separated. The oxides of manganese and iron so obtained are by subsequent turning over brought into contact with other portions of sulphide of calcium of the soda-waste, and are again converted into their respective sulphides, which give up their sulphur a second time in the way already described. The process is continued so long as there remains any sulphide of calcium from which it is sought to separate sulphur in the manner explained. The sulphur thus liberated is taken up by another portion of the sulphide of calcium of the soda-waste, and a polysulphide of calcium results from the combination, which is soluble in water. The formation of polysulphide continues as long as other portions of the original sulphide of calcium go on yielding up their sulphur to generate the sulphides of manganese and iron.* In this way almost the whole of the sulphide of calcium originally contained in the soda-waste is converted into polysulphide of calcium, hyposulphite and oxysulphide of lime, all of which are easily dissolved in water. Something like four or five days are required to effect these changes. These soluble salts are separated from the insoluble portions of the mass exactly in the same way as the ball alkali is treated for obtaining the soda it contains. Vats resembling in construction those of the soda works, and of a capacity equal to the daily production of soda-waste, are placed near the locality in which the preceding stage of the process has been effected, and in a very speedy manner the polysulphide and other salts are run off as a deep orange yellow solution, hereafter denominated the yellow liquor.

The composition of the insoluble portion is as follows:—

$CaOSO_2$	66·248
$CaOCO_2$	1·320
CaO	20·982
Fe_2O_3 and Al_2O_3	7·000
MnO	1.500
Insoluble	2·800
	99·850

As a refuse this substance will be recognised as being of an inoffensive character to the neighbourhood so far as any subsequent chemical action is concerned. Unlike the original soda waste it contains no ingredient liable to oxidation; it cannot therefore give off any of those unpleasant compounds which more or less are to be found in the vicinity of all alkali works. It is, moreover, not unreasonable to expect that a matter consisting chiefly of $CaOSO_2$ and CaO may be found useful as a stimulant to various descriptions of soils, and thus the whole of the S used in the soda process in one shape or another may be rendered useful instead of being a nuisance, as is the case at present.

The residual products from the bleaching powder works are received into a tank so built that free hydrochloric acid does not destroy the structure. By this means any insoluble portions are separated, and the clear liquid is run off into an adjoining cistern.

To this acid solution of chloride of manganese and iron, is added that of the polysulphide of calcium and lime compounds of sulphur, obtained in the manner previously given. The presence of free hydrochloric acid causes an immediate precipitation of all the sulphur, free from the sulphide of calcium, and the accompanying substances containing sulphur; and the addition of the yellow liquor is continued until the first appearance of a black colour, indicative of all the free acid being neutralized, and the first portion of iron from the chlorine residuum commencing to be precipitated. The precipitated sulphur is removed from the liquid, and the greater portion of the accompanying water is separated by pressure. After this the remainder of the moisture is expelled by a very low heat, and the sulphur is then employed for producing sulphuric acid.

It is obvious from what has preceded that the chlorides of manganese and iron must be left in the solution from which the free hydrochloric acid has just been removed in precipitating the sulphur; and it is in this way that the neutral solutions of these metals are obtained which are required for operating upon subsequent portions of the soda-waste.

This process has been in operation at Dieuze for some months, and at the present moment by its means about one and a half tons of sulphur are being recovered daily. It will be seen that no new material is required, the only ingredients being the two waste products from the manufactory itself. The apparatus employed is of a most simple character, consisting almost entirely of tanks on which the expense for maintenance will be a mere trifle—in fact the whole cost is one of labour, which at the Dieuze works amounts to something like 40s. per ton on the sulphur obtained.

Supposing 40 per cent. of the sulphur used in this kingdom to be thus recovered, the annual saving this process is capable of effecting will amount to a considerable sum.

Instead of employing the "yellow liquor" and the chloride of manganese in the way set forth in this paper, an attempt has been made at Dieuze to employ both as a means of recovering manganese, a desideratum with bleaching powder makers as eagerly sought for as the regenerating of sulphur has been with the soda manufacturer. I shall with your permission proceed to describe the process which the owners of the establishment assured me promises to be a success.

The acid solutions from the bleaching powder works, being all required in order to precipitate sulphur by means of the free hydrochloric acid, contain a consider-

---

* Along with this formation of polysulphide of calcium. there goes on at the same time a generation of hyposulphite and oxysulphides of lime due to the liberation of oxygen from the metallic oxides at the moment of being again converted in sulphides.

able quantity of neutral chlorides of manganese, and will remain on hand. To such portions of these neutral chlorides as are not used in the sulphur process itself, yellow liquor is added in a suitable tank so long as a black precipitate falls, which is variable in quantity with the varying composition of the manganese used. The black precipitate consists of sulphide of iron and free sulphur, which can be collected and burnt in an ordinary furnace for burning pyrites.

The iron being thus all separated from the metallic solution, a fresh quantity of yellow liquor is added, by which all the manganese is thrown down, the precipitate consisting of some free sulphur and sulphide of manganese.

The sulphide of manganese is burnt in the same way as that of iron, but the residue, instead of being all oxide, as is the case when the sulphide of iron is under treatment, is composed of protoxide and binoxide of the metal mixed with a certain quantity of sulphate of manganese. The oxides are separated in the usual way by water, and being almost chemically pure, are of great value to the glass-makers, to whom the presence of the iron usually found associated with the manganese of commerce, is a subject of great inconvenience.

The sulphate of manganese as a concentrated solution is added to nitrate of soda in quantities denoted by the equivalents. When heated, decomposition takes place; nitrous acid is given off, which may be used in the sulphuric acid chambers, or otherwise disposed of; and the residue consists of sulphate of soda and the protoxide and binoxide of manganese, which latter represent, so far as available oxygen is concerned, a manganese amounting to 65 to 70 per cent. of binoxide. The oxides of manganese are separated from the sulphate of soda in the usual way by washing with water, and both used for any purpose to which these two substances are commonly applied.

I may add that these operations have been carefully examined by some of the leading men of science of France, both in their practical and scientific relations, and that in the recent adjudication of prizes at the International Exhibition, at Paris, the inventors had a gold medal awarded for the service they are considered to have rendered to the industry of their country.

THE PHYSIOLOGICAL ACTION OF THE METHYL COMPOUNDS.*

BY DR. B. W. RICHARDSON, F.R.S.

The author opened by briefly recapitulating the work of the previous reports, and by noting several facts showing in a satisfactory manner the practical good that had followed their publication. Passing to the methyl compounds, the substances now to be considered, he said they were of unusual interest, inasmuch as the poisonous gas known as fire-damp, and the beneficial agent chloroform, were included in the group. He then divided the substances to be described, in regard to their physiological action, into two distinct groups, with their chemical constitutions or characters—giving first in detail a list of the methyl series as follows:—

Methylic alcohol.
Hydride of methyl; marsh gas; fire-damp.
Chloride of methyl.
Iodide of methyl.
Bromide of methyl.
Acetate of methyl.
Methylic ether.
Nitrite of methyl.
Nitrate of methyl.

The methylene series was given as follows:—

Chloroform (Terchloride). Tetrachloride of carbon.
Bichloride of methyl.

Dr. Richardson next discussed the action of the above substances in detail. The following is an abstract of his observations:—With regard to alcoholic fluids, he observed that the physiological law was that the period of time required by these bodies to produce their effects, and the period of time required for recovery, turned altogether on the boiling point of the fluid used. This was so certain that when the boiling point of one fluid and its action were known, the action of other fluids might be predicted from their boiling point. The explanation was simple. The alcohols taken into the body did not enter into any combination which changed their composition, but passed out of the body, chemically, as they entered it, and their evolution, and the time of their evolution, was the mere matter of so much expenditure of force, caloric, to raise them and carry them off. He had tested this, and found that intoxicated animals recovered more or less quickly according to the temperature in which they were placed —those in the higher degree returning the sooner to their normal condition. The practical lessons were, that in alcoholic poisoning of the human subject the most important condition for recovery was a high temperature; and that as methylic alcohol was more rapid in its action and much less prolonged in its effects than common alcohol, it could be used with great advantage by the physician in all cases where he felt an instant demand for alcohol. All alcoholic bodies are depressants, and although at first, by their calling injuriously into play the natural force, they seem to excite, and are therefore called stimulants, they themselves supply no force at any time, but take up force, by which means they lead to exhaustion and paralysis of power. In other words, the calorific force which should be expended on the nutrition and sensation of the body is expended on alcohol. Dr. Richardson added to his recommendation of methylic alcohol as a medicine the facts that when quite pure it was very palatable, and that it mixed easily with either hot or cold water.

The Hydride of Methyl.—The Hydride of Methyl occurs naturally in the form of fire-damp in mines, and as marsh gas on land. It is made artificially by heating together in a strong flask acetate of soda, caustic potash, and well dried lime. For physiological experiments the Hydride of Methyl can only be administered by inhalation. It is a pleasant gas to inhale, producing no irritation nor yet giving rise to any of those feelings of excitement which are induced by nitrous oxide gas or the vapour of chloroform. It might therefore be ranked, as Mr. Nunneley had long ago ranked it, as an anæsthetic; but, as its effect was evanescent, and the quantity of gas required to produce an effect was very great, it was practically valueless for this purpose. Dr. Richardson then proceeded:—As this gas is often a cause of death in mines, I thought it was worth inquiry —What percentage of it would prove fatal in the air? I therefore had constructed a glass chamber, through which an atmosphere charged with various quantities of the gas could be passed. To my surprise, I found that even pigeons—animals peculiarly susceptible to the influence of narcotic gases—could live in an air charged with not less than thirty-five per cent. of the gas, for the space of half an hour; while I could myself inhale the air coming from their chamber with the utmost ease. When at last by pushing the gas further,

---

* Read in Section D, British Association.

death is induced—it comes as a very gentle sleep, so gentle, indeed, that it is difficult to say when the action, either of the circulation or of the respiration, is over. The lungs are left with the blood in them, the heart has blood on both sides, and the blood itself retains its natural character. The death is by the slow negation of breathing. We may gather from these facts many important lessons in regard to the risks and dangers of miners from fire-damp. I should think it is almost impossible that any body of men, or any men who were awake in a mine, could be so entrapped with fire-damp only as to die in the absence of an explosion. In accidents where this seems to have occurred, I should imagine that with the fire-damp there is also evolved carbonic acid gas. I can, however, imagine after an explosion, when the mine becomes for a moment a great vacuum, that there would be sufficient entrance of the gas to produce a fatal atmosphere. In such case death would be prolonged, but as easy as sleep; two truths, which in cases of accident should inspire thankfulness and hope—thankfulness that those who thus die for us suffer little; hope as to the possibility of rescue, which should not for days be abandoned. The best direct means of recovery of those under the influence of fire-damp is exposure to heated air, and the administration of warm nourishing drinks, such as milk. Alcoholics do decided harm. From this point the author proceeded with a description of the action of chloride of methyl, the iodide, bromide, and acetate, methylic ether, nitrite of methyl, and the nitrate, over which we must pass, to record his more general researches on chloroform and its allies.

Methylene Compounds.—Dr. Richardson spoke at length on these compounds as anæsthetics, describing the nature and action of chloroform, tetrachloride of carbon, and bichloride of methylene (with which he put a pigeon to sleep under a glass shade). He had been led to the conviction that the cause of death from chloroform was in every case due to the arrest of nervous function, and that the idea of any direct action of the agent on the muscular structure of the heart was without foundation. He had conducted eighty-seven experiments specially to determine the direct influence of chloroform on the heart, and found in every case that organ capable of reaction on its exposure to air, while the lungs were always bloodless, white, and collapsed. The best means of restoration in impending death from chloroform was the introduction into the lungs, by artificial respiration, of air heated to 130° Fahrenheit. For doing so a small pair of handbellows connected with a thin tube of platinum in a coil was found to answer well, as with a spirit lamp the coil could be instantly made hot. It was only necessary to inject the air through one nostril. The tetrachloride of carbon had recently been brought into use as a substitute for chloroform. With regard to it Dr. Richardson said—As this substance is now gaining importance, I have thought it proper to subject it to very careful experiment, and I feel it my duty to state, both on theoretical and practical grounds, that it is far more dangerous than chloroform, and if it were as generally used it would act fatally in a much larger number of cases. In its action it presents the same four stages as chloroform, but the second stage is more prolonged and intensified. In one animal, a rabbit, tetanic convulsion of an extreme character was presented during this stage. But the worst feature in the administration of this body is the slowness of its elimination—a slowness fully accounted for by the boiling point. Saturating the nervous centres, and expending their force to the fullest, it kills far more quickly and determinately than chloroform, and so completely is motion paralyzed that the muscles scarcely respond to galvanism five minutes after dissolution. In order to make an exact comparison, and it is from this comparison I draw the results arrived at—I placed animals of the same kind, at the same time, at the same temperature, in chambers of the same size, and administered the same doses of chloroform and of the tetrachloride of carbon. Pigeons and rabbits alike gave evidence of the more severe effects of the latter substance. In this opinion my friend Dr. Sedgwick, who has rendered me valued aid in these inquiries, entirely coincides.

The Bichloride of Methylene.—The last compound on our list is of great interest, from the circumstance that it promises to be a new and valuable anæsthetic. In experimenting with chloride of methyl in ether, I was so struck with its good action that I asked Mr. Robbins, the chemist who had prepared the compounds for me, to endeavour to find, from the methyl bodies, a more stable compound, having similar physical properties. In a few days he brought me the fluid I now place before the Section, made for him by Dr. Versmann. This fluid is the bichloride of methylene. It is formed by the action of sulphuric acid on zinc in chloroform, and it differs from chloroform in that one atom of chlorine is replaced by an atom of hydrogen. Its boiling point is 88° Fahr., and the odour of its vapour is sweet, and much like that of chloroform. On testing it physiologically, I found it to be a gentle and perfect general anæsthetic. Under its influence animals lapse into the third stage of anæsthesia with the slightest exhibition of the stage of excitements. The insensibility is deep and well sustained, and the recovery quiet and good. (Dr. Richardson here showed the experiment already mentioned of putting a pigeon to sleep.) In some experiments, in order to see the extreme effect, I have carried the administration to the extent of arresting the phenomena of life. I have thus learned that the respiration and circulation under the last action of this agent cease simultaneously, and that the muscles retain their irritability for even an hour after death. The lungs are left with blood in the respiratory circuit, both sides of the heart are charged with blood, and the blood itself remains unaltered in physical property. Compared with other anæsthetics, the bichloride of methylene appears to me to combine the anæsthetic power of chloroform with the safer properties of ether. It is too early to speak positively on this point, but if the expectation be fulfilled, the perfection of a general anæsthetic will have been obtained for the benefit of the world. And, even should this happy result not be accomplished, the way at least is paved towards the discovery of some intermediate body which shall answer to the required physical demand. In reviewing the facts connected with the physiological action of the methyl series, we gather that, according to their composition, they exert certain definite influences on different parts of the nervous organism. The oxide produces an influence specifically its own, that of slowly paralysing the motor function without destroying common sensibility. The nitrite and nitrate rapidly paralyse the centres of motion, while the chloride, and the iodide, together with the substitution chlorine compounds, not only paralyse motion but also destroy sensation. I conclude this report with one other observation. At first sight it may seem that the isolation of the phenomena produced by special agencies, and the discovery of a new anæsthetic are sufficient characteristics of this research. With every respect, I submit that a broader question is involved. At the meeting at Birmingham I suggested, almost with a feeling of fear, that out of these studies might spring up a fixed principle of therapeutic discovery. Now, I have the conscious happiness of knowing that the hypothesis was correct. I feel convinced by this longer experience that by continued labour we shall be able to pronounce the precise physiological meaning and value of all the organic compounds, to extend the knowledge of curative action of these compounds to every condition of disease that is physically remediable, and to bring positive Science of Therapeutics to a position that shall stand out as a leading fact in the scientific advancement which the British Association so fervently encourages, and which at once solidifies and beautifies the progress of the present age.

ON A REAL IMAGE STEREOSCOPE.*

BY J. CLARK MAXWELL, F.R.S.

In all stereoscopes there is an optical arrangement by which the right eye sees an image of one picture, and the left eye that of another. These images ought to be apparently in the same place and at the distance of most distinct vision. In ordinary stereoscopes these images are virtual, and the observer has to place his eyes near two apertures, and he sees the united images, as it were, behind the optical apparatus.

In the stereoscope which I have had made by Messrs. Elliott Brothers the observer stands at a short distance from the apparatus, and looks with both eyes at a large lens, and the image appears a real object close to the lens.

The stereoscope consists of a board about two feet long, on which is placed—1. A vertical frame to hold the pair of pictures, which may be an ordinary stereoscopic slide turned upside down. 2. A sliding piece near the middle of the board, containing two lenses of six feet in length, placed side by side, with their centres about one inch and a quarter apart. 3. A frame containing a large lens of about eight inches focal length and three inches diameter.

The observer stands with his eyes about 2 feet from the large lens. With his right eye he sees the real image of the left-hand picture formed by the left-hand lens in the air close to the large lens; and with the left eye he sees the real imagine of the other picture formed by the other lens in the same place. The united images look like a real object in the air close to larger lens. This image may be magnified or diminished at pleasure, by sliding the piece containing the two lenses nearer to or farther from the picture.

ON THE ANALYSIS OF CAST-IRON.

BY EDMUND G. TOSH, PH.D.

(Continued from page 172, American Reprint, Oct., 1867.)

Estimation of Graphite. 2 to 3 grammes of iron were treated with dilute hydrochloric acid, and when solution approached completion a considerable quantity of strong acid was added to separate the last portions of iron and manganese. The insoluble matter, consisting mostly of graphite, was collected on a carefully weighed filter, washed with hot water, dilute hydrochloric acid, solution of caustic soda, and hot water again, successively, lastly with alcohol and ether to remove oily hydrocarbons as recommended by Max Buchner.* By washing with dilute acid and with alkali, iron and silica or oxide of silicium were separated. After drying at 120° C. the filter and graphite are weighed and burned away. The small residue (a mere trace of silica or titanic acid) is weighed, and this weight subtracted from the first gives the amount of graphite. The results obtained agree very closely, as shown in the two following cases:—

1. 2·36725 grms. iron gave 0·08375 grm. insoluble matter, containing 0·013 grm. incombustible residue. Graphite per cent. =2·978.

2. 2·991 grms. iron gave 0·1095 grm. insoluble matter containing 0·01725 grm. incombustible residue. Graphite per cent. =3·0842.

In washing the graphite with solution of soda, there was always a brisk effervescence, due according to Schafhäutl † to the oxidation of oxide of silicium to silicic acid, by decomposition of water, with consequent liberation of hydrogen.

The difference between the quantities of graphite and of total carbon, is the amount of carbon in the combined state.

Estimation of Silicium. About 2 grammes of the iron were dissolved in aqua regia, and evaporated to dryness. The insoluble matter was collected, washed, dried, ignited, and cautiously deflagrated with nitrate of potash. Graphite is thus quickly burned away: the fused mass is extracted from the crucible by means of water. The alkaline silicates in solution are decomposed by hydrochloric acid in considerable excess, and the whole evaporated to dryness. To the dried mass a few drops of hydrochloric acid are added, and afterwards water. The insoluble silica is filtered off, washed, dried, and ignited till quite white. From its weight the proportion of silicium in the iron may be deduced.

Estimation of Sulphur. About 3 grammes of the iron were dissolved in nitric acid, with the occasional addition of a few drops of hydrochloric acid, and evaporated to dryness. The residue is dissolved in the least possible quantity of hydrochloric acid, and water added. The sulphuric acid in the clear, filtered solution is precipitated by chloride of barium. After standing 24 hours, the sulphate of baryta is collected. It is generally contaminated with a little iron which may be removed by treatment with dilute hydrochloric acid.

Estimation of Phosphorus. 3 grammes of the iron are dissolved in aqua regia, the solution evaporated to dryness, and the insoluble matter filtered off. The perchloride of iron solution is reduced to the state of protochloride, by heating with sulphite of soda. Although perfectly reduced, the solution still retains a yellow colour due to dissolved organic matter. All excess of sulphurous acid is boiled off, a little perchloride of iron is added, and the solution cautiously neutralised by means of carbonate of soda or ammonia, till the precipitate formed does not dissolve again. This small portion of peroxide of iron containing all the phosphoric acid, is filtered off, washed, redissolved in a little hydrochloric acid, and the phosphoric acid precipitated as ammoniophosphate of magnesia, the iron being held up in the ammoniacal solution by citric acid.

Estimation of Manganese.—3 to 4 grammes of

---

† Journ. f. prakt. Chem. lxvii. p. 257.

iron are dissolved in aqua regia; the solution is largely diluted and filtered, and neutralised with carbonate of soda or ammonia till of a deep brown colour. The iron is precipitated by acetate of soda, and the solution immediately boiled. The large precipitate settles quickly, the clear liquid is poured off and filtered. After three washings by subsidence and decantation, the precipitate is thrown on a large filter and again washed. The bulky solution containing all the manganese is evaporated to small volume and refiltered. The manganese is first precipitated by sulphide of ammonium, the sulphide collected and washed with sulphide of ammonium water, redissolved in hydrochloric acid, the solution boiled, and the manganese reprecipitated as carbonate by carbonate of soda, filtered off, washed, dried, and ignited till of constant weight, showing its perfect conversion into Mn_3O_4.

Titanium.—The estimation of this element in any substance is somewhat uncertain, and its determination in pig iron can scarcely be accurately accomplished. Its detection in iron is not difficult. A considerable quantity (5 grms.) of the specimen is treated with dilute hydrochloric acid, and insoluble collected, graphite burned off, and the residue freed from silica without loss of titanic acid, by heating with a mixture of hydrofluoric and sulphuric acids as recommended by Riley.* After driving off sulphuric acid, titanic acid is left behind, which may be distinguished by the violet reaction it gives with microcosmic salt and a little tin in the reducing flame of the blowpipe.

It may be approximately estimated in the following way. About 6 grammes of iron are dissolved in hydrochloric acid, and the whole evaporated to dryness. The dried mass is moistened with hydrochloric acid, water added, and the solution filtered. Part of the titanium exists in the solution (a) and part in the insoluble (b). The solution, if containing much perchloride of iron, is reduced by sulphite of soda, the excess of sulphurous acid boiled off, a little perchloride of iron added, and the titanic acid precipitated in combination with the sesquioxide of iron thus introduced, by means of carbonate of soda, as in the estimation of phosphorus. The small precipitate is quickly filtered off, washed, dried, ignited, and carefully set aside.

From the insoluble matter (b) graphite is burned off, and the silica is removed by hydrofluoric acid in the presence of sulphuric acid. To the residue after this treatment the small ferruginous precipitate from (a) is added, and the whole fused with bisulphate of potash. When cool the fused mass is extracted with cold water, and from the clear filtered solution, titanic acid and iron are precipitated by ammonia; the precipitate is slightly washed, and sulphide of ammonium added. The sulphide of iron thus formed is dissolved by sulphurous acid, while the titanic acid mixed with sulphur is undissolved, and may be collected, ignited, and weighed, after which it should be tested as to its purity.

Nitrogen was estimated by the following process of Boussingault.† 5 grammes of the iron under examination are slowly dissolved in very dilute hydrochloric acid. By this means a part of the nitrogen is converted into ammonia, and exists in the solution as chloride of ammonium, and another portion remains in the insoluble, probably combined with the titanium. This insoluble is collected, and the filtered solution is treated in a capacious flask with a considerable excess of caustic lime and boiled. A tube connected with the flask by a tight cork, dips into dilute hydrochloric acid, by which the liberated ammonia is absorbed. Nitrogen is estimated in the graphitic matter insoluble in acid by burning with soda-lime, the ammonia formed being also absorbed by dilute hydrochloric acid. Both solutions are now brought together, evaporated to small bulk, chloride of platinum added, the small precipitate collected, washed with alcohol, dried, ignited, and the remaining platinum weighed, from which the amount of nitrogen may be calculated.

Nickel, cobalt, and copper were carefully sought for by operating on large quantities of the various specimens of iron, but evidence of their presence could not be obtained. 63 grammes of iron were deflagrated with a mixture of carbonate of soda and nitrate of potash, the contents of the crucible dissolved out with hot water, and the highly alkaline solution filtered off from the large quantity of sesquioxide of iron. This solution was first neutralised with hydrochloric acid, chloride of ammonium, ammonia, and sulphate of magnesia added, and any phosphoric and arsenic acids allowed to precipitate during 24 hours. The precipitate was collected, washed with ammonia water, dissolved in acid, the solution heated, and sulphuretted hydrogen passed through it. A very small light yellow precipitate formed, which proved to be sulphide of arsenic.

In all determinations of iron, where practicable, I have used the volumetric method by means of bichromate of potash, first proposed by my former professor, Dr. Penny, of Glasgow, which is I think preferable to that of Margueritte, where permanganate of potash is employed. Bichromate is much more stable than permanganate, and the strength of the solution only requires to be determined once. Besides, in the estimation of iron by Penny's method, there is no fear of the evolution of chlorine, which has to be so carefully guarded against in Margueritte's process.

THE ELECTRIC INDUCTION OF MR. HOOPER'S INSULATED WIRES, COMPARED WITH GUTTA-PERCHA INSULATED WIRES, FOR TELEGRAPH CABLES.*

BY WILLIAM HOOPER.

The author referred to the relation existing between the different properties of insulated wires arising from induction. He showed by an extensive series of experiments that an intimate connection exists between the effects of electrification and electrostatic induction, and that the penetration of electricity into the substance of an insulator, when measured by the residual discharge, is a function of the electro-static capacity, and not simply of resistance. He has also shown that the effects of electrification are increased nearly in the same proportion as the interior inductive action is reduced.

The results render it extremely probable that in rapid signalling through long circuits, as by "waves," the rate of transmission attainable is not increased or diminished in the simple proportion of the electrostatic capacities, but in a ratio compounded of it and the interior resistance to inductive action.

---

* Journ. Chem. Soc. Vol. p. 311.

† Comptes Rendus, T. lii. p. 1088.

* Read before the British Association, in Section A.

This is a matter of serious consideration, for the interior induction, unlike the surface induction, is not reduced by an increased thickness of insulator, which points strongly to the practical advantage derivable from Mr. Hooper's dielectric over gutta-percha in every respect for induction. These results are verified by Mr. Latimer Clark, Mr. Varley, Professor Sir W. Thomson, and Mr. Fleeming Jenkin.

So much superior is Hooper's dielectric to gutta-percha for insulation, that, taking the core of the electric telegraph cable connecting Ceylon with India as an illustration, at 75° Fahrenheit, the temperature at which cores are tested, it would require a core nearly 2 feet diameter of gutta-percha to equal ·38 inch diameter of Mr. Hooper's insulator (that is, 200 lbs. of Hooper's insulator is equal to 576,000 lbs. of gutta-percha), the same conductor being used in each, to obtain the same degrees of insulation.

ANTISEPTIC PROPERTIES OF THE SULPHITES.*

Dr. Richardson read a paper by Dr. Polli, in Section D, "On the Antiseptic Properties of the Sulphites." He stated that he was afraid he might not make a good representative of his learned friend, Dr. Polli of Milan. However, as he had long communicated with Dr. Polli on the subject, and knew well what that gentleman meant, he (Dr. Richardson) had chosen, instead of trying to present the paper as a whole, rather to give the facts presented by him as the results of extended observations. Sulphurous acid was said to be the most active agent in preventing or arresting all organic fermentation. As the acid, however, was not sufficiently applicable in experiment, Dr. Polli had undertaken an investigation as to the action of the sulphites of lime, hyposulphite of magnesia, sulphite of magnesia, sulphide of soda, and granulated sulphite. These substances were found to possess all the properties of sulphurous acid, with the advantage that their action was more uniform and certain and constant. In experimenting on animals and himself, he found that large doses could be taken without risk. On killing animals treated with sulphites, and others not so treated, he found that the former were most slow to decompose, and, indeed, remained quite fresh when the others were putrescent and offensive. Another series of experiments showed that in one class the administration of the sulphites, was sufficient to effect a more or less rapid cure in cases where blood-poisoning was present, as in fevers. Dr. Richardson distinctly mentioned, however, that Dr. Polli was anxious to have it clearly stated that he did not attribute this to any curative power in the sulphites, but to the fact that they arrested decomposition, and by so doing allowed the animal to recover by the recuperative power existing in its own constitution. The author thought his observations conclusive as to the excellent influence of the sulphites on the septic diseases, and remarked that it was for the purpose of thus benefiting others that he had brought his researches under the attention of the scientific world. Dr. Richardson laid some of the sulphites before the Department, and mentioned that he would be glad to let physiologists have four or five ounces of any of them for the purpose of experimenting, and that physicians might also receive a small quantity for hospital practice.

ON A NEW FORM OF DYNAMO-MAGNETIC MACHINE.*

BY W. LADD.

It is now thirty-six years since Faraday first published his celebrated "Researches in Electricity and Magnetism;" the foundation then laid has been receiving additional strength as the superstructure has progressed. Faraday has gone to his rest, but the name he always tried to hide behind his philosophy will shine brighter and brighter, until the top stone is raised in future ages. The machine I am about to describe is a part of that superstructure. The repeated application to me for a machine that would give a sufficient light for the purposes of lecture demonstration and would dispense with the galvanic battery, has induced me to give considerable attention to the subject, and I must leave you to judge how far this machine meets not only that requirement, but also that of lighthouse illumination.

Perhaps the most powerful magneto-electric machine was that constructed by Mr. Wilde, the electro-magnet receiving its charge from sixteen permanent steel magnets, but Siemens and Wheatstone have shown that the residual magnetism left in soft iron, after being under the influence of a battery, or permanent steel magnets, can be augmented from the currents generated by itself, by merely applying dynamic force to the revolving armature, containing a coil of copper wire, the terminals of which are connected with the wire surrounding the electro-magnet; and although great effects were produced *in* the electro-magnet, the current itself could only be made available by its partial or total disruption—in the former case diminishing the power of the electro-magnet, and in the latter reducing it to its normal condition. But in the machine I have constructed, the power of the electro-magnet is kept up, whilst a separate current, to be applied to any useful purpose, can be drawn off by means of an independent arrangement.

It consists chiefly of two plates of iron; to both ends of each plate is fixed a portion of a hollow cylinder; these plates are then placed a certain distance apart, and insulated from each other in such a manner that the cylindrical pieces will form two hollow circular passages; into these spaces two armatures (known as Siemen's armatures) are placed. The plates are surrounded by a quantity of stout copper wire, connected together, the two terminals of which are brought into connection with the commutator of the smaller armature, so that each change of polarity in the armature will augment the magnetism. When the machine is first made it is only requisite to pass a current from a small cell of Smee's or any other element, for an instant, to give the iron a polarity; it will then retain a sufficient amount of magnetism for all future work.

If the armature in connection with the electro-magnet is made to rotate, there will be a very feeble current generated in it; this passing round the electro-magnet, will increase its power with every additional impulse. It will thus be seen that the only limit to the power of the machine is the rapidity with which the armature is made to rotate, which is entirely dependent on the amount of dynamic force employed. But the great improvement in this machine is the introduction of the second armature, which, although it takes off very powerful currents, generated in its wire by the increas-

---

* Read before the British Association, in Section A.

[English Edition, Vol. XVI., No. 408, pages 169, 170.]

ed magnetism, does not at all interfere with the primary current of the electro-magnet.

The machine now at the Paris Exhibition measures about 24 in. in length, 12 in. in width, and stands 7 in. high; but this being imperfectly constructed as to its proportions, the results obtained are, no doubt, much less than they would be with a properly constructed machine. Still, I found it would keep 50 in. of platinum wire, ·10 in. diameter, incandescent, and when a small voltameter was placed in circuit with the second armature it would give off 250 cubic centimetres of gas per minute, and in connection with an electric regulator would give a light equal to about thirty-five Grove's or Bunsen's elements, the driving power expended being less than one horse.

I have now to describe a machine on the same principle as that just noticed, but which, instead of having two independent armatures running in separate grooves has two armatures fixed end to end, so as to appear like one continuous armature, but so placed with reference to each other that their magnetic axes shall be at right angles. By this arrangment there is only one opening required for the armature, enabling us to take full advantage of the horse-shoe form of electro-magnet. The shoes of the electro-magnet and armatures are so proportioned to each other that there is an actual break in the magnetic circuit with reference to each armature alternately, but by their disposition at right angles there never is an actual break in the complete magnetic circuit, but simply a shifting of the principal portion of the magnetic force from one armature to the other at the precise moment required to produce the best effect. The mechanical advantages obtained by this disposition of parts must be at once obvious, as one pair of bearings and set of driving gear is dispensed with, and from the fixing of the two armatures together the currents are made to flow perfectly isochronously. It may be found of advantage to vary the angle of position of the armatures with reference to each other, according to the speed at which they are driven, so that the current given off by the exciting armature may at the precise moment exert its full effect upon the electro-magnet, and thus produce the best effect in the second armature.

ON THE COMMERCIAL ANALYSIS OF SOME OF THE PRODUCTS AND MATERIALS OF THE ALKALI MANUFACTURE, Etc.

BY C. R. A. WRIGHT, B.SC., F.C.S.

[Continued from page 226, American Reprint, Nov., 1867.]

III. **Soda Ash.**—The commercial valuation of soda-ash is usually restricted to the determination of the percentage of "available alkali" contained therein, by this term being meant the total Na_2O contained in a state capable of saturating a strong acid, as sulphuric; and hence including hydrate, carbonate, aluminate, silicate, sulphide, sulphite, and hyposulphite. The analysis is usually performed by adding the standard acid to the hot aqueous solution of an known weight of ash until a slight acid reaction is obtained; by this means all calcium contained, and Al_2O_3 contained as aluminate, are estimated as though they were soda. Practically this error is of slight importance; it may be readily avoided by addition of a very slight excess of acid along with some litmus tincture, then adding a slight excess of standard sodium carbonate solution, boiling and filtering from the precipitated lake and $CaCO_3$: the excess of soda added is now again determined by the standard acid, and thus the exact amount of acid used to saturate the Na_2O present in the "available" state is known. An abuse, however, that has long been practised in the soda trade in connection with this is the following:—The equivalent of sodium is considered to be 24 (instead of 23·04—Stas). Hence by varying the mode of calculation, a varying error is introduced, the available alkali being always represented as more than it really is. If sodium be thus calculated, the error is $+\frac{0{\cdot}96}{24}$ or 4·0 parts in 100: if Na_2O be calculated, the error is $\frac{64-62{\cdot}08}{64}$ or 3·0 parts in 100: while if Na_2CO_3 be calculated, it is $\frac{108-106{\cdot}08}{108}$ or 1·8 parts in 100. Hence according to the plan employed in determining the standard of the acid used, according as soda salts are thus used, or other substances, an error of from 0·9 to 2·0 per cent. is introduced in the valuation of a 50 per cent ash. Hence arises the custom in many alkali works of invoicing the sales of ash at from 1 to 2 per cent. higher than their real strength, it being known that the purchaser will accept the analytical certificate calculated on this erroneous basis. This practice, which is neither more nor less than a barefaced fraud, is by no means universal, nor is it known to many of the purchasers of soda ash; in certain districts, however, it prevails, and is a constant source of vexatious complaint whenever the purchaser happens to employ on his own side a more conscientious analyst. The writer has known soda ash of identical quality invoiced part to one customer as containing 48 per cent., part to another as 49 per cent., and part to a third as 50 per cent., the actual percentage being 48½; the separate consignments being reported also in these different strengths by the analysts in the different towns to which the goods were sent; inasmuch as soda ash is usually valued as so much per cent. per cwt.,—this amounts to a direct fraud on the purchaser. It sometimes happens that an analyst, known to object to this system, finds that his connection for the analysis of soda ash becomes *nil*, being transferred to some less scrupulous rival.

When the exact composition of a sample of soda ash is required, the following method may be adopted.

(*a*). A known weight is heated to 150°—200°C., and the loss of weight considered to be moisture.

(*b*). The residue of (*a*) treated with hydrochloric acid leaves sand and insoluble matters, and in the filtrate the SO_4 may be estimated volumetrically, or better gravimetrically, by barium chloride.

(*c*). The CO_3 present is estimated in Mohr's apparatus, or in Fresenius' and Wills', with the addition of some potassium chromate.

(*d*). A known weight is treated with water, and the solution evaporated to dryness with hydrochloric acid; thus the SiO_3 is determined; the filtrate from this with ammonia throw down alumina, from which the Al_2O_4 (as aluminate) is known.

(*e*). The insoluble residue of (*d*) with hydrochloric acid and ammonia, gives the Fe_2O_3 and Al_2O_3 (not as aluminate), the filtrate from this with ammonium oxalate gives the calcium (usually only traces).

(*f*). A known weight is dissolved in nitric acid, and the Cl estimated by a standard silver solution.

(*g*). A known weight dissolved in water is oxidized by chlorine, and the sulphate thus formed determined; a known weight is dissolved in water, and the solution divided into two equal parts; in one the iodine required to yield a blue colour when starch and acetic acid are added, is determined, to the other zinc sulphate is added, and in the filtrate the iodine required after removal of sulphide is again determined; from these data on the sulphide, sulphite, and hyposulphite are calculable.

(*h*). The total "available alkali" is determined, the error due to the alumina of the aluminate being eliminated as previously mentioned; subtracting from this calculated as sodium, the sodium corresponding to the $SiO_3Al_2O_4$, sulphide, sulphite, hyposulphite, and CO_3 found, the difference is calculated as hydrate; this may be checked by adding barium chloride to a known weight, aud determining the amount of acid required to neutralise the filtrate: rather more hydrate is usually indicated by this mode than that really present, owing to the presence of a portion of aluminate, hyposulphite, etc., incompletely thrown down by the barium salt.

Carefully executed analyses according to this method have yielded the writer results adding up to 99·8—100·1.

When ferrocyanide is present, it may be estimated by dissolving a known weight of ash in hydrochloric acid, and adding ferric chloride; after standing some time, the precipitated Prussian blue may be well washed, treated with pure potash, and the ferrocyanide determined in the solution by permanganate.

(IV.) **Bleaching Powder.**—The commercial estimation of bleaching powder only extends to the estimation of the hypochlorite contained therein; the result being, however, calculated as so much per cent. of "available chlorine." Of the numerous methods proposed for the determination of the hypochlorite, the one usually employed in the trade is that depending on the amount of ferrous salt oxidised by a given weight of bleaching powder. It frequently happens, however, that instead of a perfectly pure ferrous salt (such as the ammonio-sulphate $FeSO_4 + (NH_4)_2SO_4 + 6H_2O$ precipitated by alcohol), the ordinary "protosulphate of iron" of the druggists is used, discoloured crystals being of course rejected; rarely does this substance contain 100 per cent. of the compound $FeSO_4 + 7H_2O$, and hence errors frequently are introduced, less chlorine being required to peroxidise a given weight of impure than of pure substance. Again, some analysts neglect to add an acid to the ferrous solution used, and hence the precipitated ferric hydrate is liable to carry down perceptible quantities of ferrous hydrate, again making the apparent amount of chlorine required less than that really requisite. When acid is added, an error is liable to be introduced by the peroxidation of part of the iron by chlorine compounds derived from chlorate that may be present; direct experiments have shown the writer that acid ferrous solutions are perceptibly oxidised by the presence of chlorate in small quantities in the course of a very few minutes, even at the ordinary temperature, although the peroxidation due to the whole of the chlorate is not manifest, until after standing some time at 20°C., or till after heating to ebullition. Lastly, the equivalent of chlorine is frequently taken to be 36 instead of 35·46 (Stas). All these sources of error tend to make the percentage of chlorine found higher than that really present; accordingly it frequently happens that analyses of the same sample by different analysts differ by 1, 2, or 3 per cent. of available chlorine; this error becomes of serious importance, it frequently happening that the analysts employed by the seller and purchaser differ in their reports, thus causing much annoyance, and possibly the rejection of the goods as not being of contract strength.

As regards the error introduced by the presence of chlorate in the sample analysed, many careful experiments on the subject have yielded the following results to the writer:—

1. Acid ferrous solutions are peroxidised by addition of a chlorate, at a rate depending on the strength of the solutions, the amount of free acid, and the temperature, the reaction taking place completely after heating to ebullition for a minute, and almost as completely after standing for upwards of half an hour at 20°C., time being, however, required for any temperature short of ebullition.
2. Acid solutions of As_2O_3, where a large excess of free acid is present, are scarcely affected by chlorate at 20°C., until after standing some hours; the reaction ensues completely on heating to ebullition for a minute, and completely in a few minutes' heating on a water bath.
3. Alkaline solutions of As_2O_3 (containing $NaHCO_3$ and free carbonic acid) are wholly unaffected by chlorate, either cold or boiling, even after several hours.
4. Acid solutions of potassium iodide (free from iodate). Iodine begins to separate even at 20°C. in a very few moments on addition of very little chlorate, and after some time much separates. Heated to 100° on the water bath, the whole of the chlorate becomes completely decomposed, after five minutes, in presence of sufficient free acid.
5. Alkaline solutions of potassium iodide are unaffected by chlorates even on long standing or long boiling.

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Doubtless the majority of your readers imagine (if they ever took the trouble to think of the matter at all, which is not very likely) that the paths of a "special correspondent" are strewn with flowers. What has he to do but to examine, compare, and write the results in as decent English as he can command? This is very true; but has it never struck you, "gentle reader," that there is, to put it mildly, a tinge of sameness about all this examining, comparing, and writing? Your correspondent would not have alluded to the subject were it not that he has fallen a victim to another set of "*concessionnaires.*" As long as one could take a chair outside the building and refresh oneself with a cup of coffee after the fatigues necessarily involved in the study of the productions of rival blacking and soda-water manufacturers, one's task was, although laborious, not without its redeeming points; but now that the chairs are removed, you must no longer expect the same regularity from your correspondent.

Our French friends here are in high glee about the Newton-Pascal affair. It will, indeed, need overwhelming evidence to disprove the mass of forged documents upon which the advocates of the Pascal theory rely. Unfortunately, the evil does not rest here. In this city there are a number of clever and not too scrupulous men of letters who delight beyond measure in mystifications of the Newton-Pascal type. Any great event in scientific, political, or artistic history is at once seized upon as a theme, and on it are erected a variety of literary edifices which, if not sound, are at least showy and attractive. To prove this it is only necessary to allude to the mass of forged letters of Marie Antoinette, upon which such opposite theories have been built. The affair of the necklace, the Man in the Iron Mask, Count Cagliostro, the Count de Saint Germain, Madame de Brinvilliers,—I could for a thousand francs obtain documents to prove any theory connected with these highly promising subjects for the skill and inventiveness of literary charlatans. At a discussion the other day upon the affair of Newton, a French literary celebrity, pressed rather hard on the question of these forgeries, stated, with the entire concurrence of the Gallic element among his hearers, that France would soon prove to the world that *all* the greatest discoveries and the grandest ideas were French. "Your English writers, what are they but imitators of us? You have invented the word "adapted" to conceal your robberies from our dramatists, and now, not satisfied with "adapting" our dramas, you "adapt" our discoveries. Your Swift and your Sternes that you pride yourselves upon so much, have they not robbed from Rabelais? They should be kicked, especially your Sternes." The roar of laughter that arose from the English portion of his hearers so disconcerted the worthy professor, that "the sitting was suspended" for some minutes; but he enjoyed the explanation which followed so thoroughly that harmony was immediately restored.

To return to our work. Messrs. Burgoyne, Burbidges, and Squire, of Coleman-street, London, have a very handsome and well-arranged collection of drugs and chemicals. They are of very fine quality. They exhibit oil of bitter almonds both in the raw state and as freed from hydrocyanic acid. Their oils of cloves, carraway, pimento, nutmegs, cubebs, pepper, etc., are apparently as good as they can be. They, like the Messrs. Howard's, exhibit a fine specimen of benzoic acid; it is in a large globe, and has a very good effect. It is not made by direct sublimation, but by boiling the powdered gum benjamin with lime and water as long as any acid remains to be extracted. The solution is then precipitated with hydrochloric acid, and the resulting benzoic acid, after being separated by filtration from the solution of chloride of calcium, is dried and sublimed. They also exhibit white crystallised benzoic acid, prepared entirely by the wet process. This kind of acid is used in Germany, and is manufactured entirely for that market. Their cyanide of potassium, prepared by Liebig's process, looks well, and is stated by the makers to contain a very high percentage of pure cyanide. There is a sample of pure nitrate of barium, which they are now manufacturing in large quantities at the price of from £35 to £40 per ton. The chloride of barium is also manufactured by this firm in a pure state at £30 the ton. They also exhibit nitrate and carbonate of bismuth perfectly free from arsenic; and potassio-tartrate of antimony in crystals and in powder. The cubebin shown is prepared from the residue left in the still after distilling oil of cubebs. There are in this case two large specimens, about sixteen inches in diameter, of piperin and caffein. Piperin forms a very easily-broken crystalline mass, and the most extreme care had to be taken to get this fine preparation safely to the Exhibition. It was suspended by India-rubber springs so as to avoid concussion, and the arrangement was then hung in gimbals like a ship's compass. Owing to this careful packing it arrived safely, and without the mass losing a single crystal.

When we think how many fine specimens, not only chemicals, but also works of art, were destroyed in transit (some by careless packing, and still more by the brutally rough usage the packages containing them received), we cannot help expressing the hope that the skill and care shown in this matter by Messrs. Burgoyne and Co. will be imitated in future by some of those exhibitors whose despair, on unpacking their cases, was so ludicrously displayed.

The very complete collection of the scale preparations of iron exhibited in this case have suffered from the prolonged exposure to light which they have necessarily undergone, and have thus lost that beautiful colour and brilliant lustre which they possessed when they first arrived.

Among the other objects interesting to Pharmaceutists, are a collection of gelatine capsules containing balsam of copaiba, castor oil, oil of male fern, and sundry other unsavoury drugs. The exhibitors were induced to undertake the manufacture of these articles owing to the low character of a vast number of the capsuled preparations found in commerce. It is well known to those behind the scenes in these matters that, owing to the viscidity of the balsam of copaiba and oil of male fern, it is a common practice among unscrupulous makers to thin them down with linseed oil in order to facilitate the process of filling the capsules. The dilution of the active ingredients of the capsules which thus takes place is often so great as to render them entirely valueless as medicines.

Messrs. Burgoyne's case is one of the handsomest and best arranged in the English chemical department of the Exhibition, and, if it contains no great novelties, at least represents in a highly creditable manner the present state of English Pharmaceutical manufactures.

Messrs. Davy, Yates, and Routledge, of Upper Thames Street, London, have also an excellent display of drugs and chemicals. Their specimen of corrosive sublimate in a dome is adapted to show the fracture, and looks well. They also show calomel in a crystalline form as prepared by the old dry sublimation process, and also as sublimed in presence of steam. The first kind becomes discoloured on exposure to light, and sometimes retains traces of corrosive sublimate; the second is free from either of these defects. The ammonio-citrate of bismuth is a comparatively new scale preparation. It is in the form of micaceous scales, containing sixty per cent. of oxide of bismuth. The fact of its ready solubility in water without decomposition, and its being "compatible" with the alkalies and their carbonates, has made this salt a great favourite with many practitioners; and, indeed, in some stomach complaints this and other preparations of bismuth appear to act almost like a charm.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, Sept. 3, 1867.

Scientific Association at Cherbourg.—Electricity of Connecting Straps in Machinery.—The Triangulation of Prussia.

The meetings of the Scientific Association at Cherbourg were terminated on the 24th of August. Nothing was neglected to increase the interest of this re-union of savants and amateurs. Visits were made to the soda and iodine works of M. Cournerie, to the military port, where the *Dunderberg*, now christened the *Rochambeau*, and where the spur of the *Atalante* is being cast; lectures were delivered on astronomy and meteorology, at which the professors attended, furnished with instruments, due to the munificence of the government; and there were also reports, memoirs, notices, and discussions on different points of the natural, physical, and moral sciences.

M. Quesnault, sub prefect of Valognes, presented a memoir in which he demonstrated that the British Isles and the small archipelago existing on the north-west coasts of France, from the Cape la Hague to Cancale point, or rather, as far as St. Malo, formed part of the Continent, and laid down a map on which all the vestiges of terrestrial vegetation existing, or supposed to exist, under the sea were shown.

M. Lenoir, director of the telegraph at Saint-Lo, called the attention of the assembly to the electricity of connecting-straps in machinery, and the dangers which might result from it in powder works.

A fortuitous circumstance added considerably to the interest attached to this meeting. Lady Franklin, widow of the celebrated explorer of the northern regions, assisted at the meetings of the 23rd and 24th ult. The noble lady had arrived on the 22nd by the American frigate the *Minnesota*, accompanied by Miss Grinnell, a young lady, the daughter of a shipowner of New York, who had fitted out at his expense two ships for the research of Sir John Franklin. At the last meeting it so happened that M. Lambert gave a description of his project of a voyage to the North Pole. This *rencontre* of Lady Franklin and M. Lambert is described as presenting a most impressive scene to the audience. Lady Franklin was to leave on the 27th on board the pleasure yacht *Leda*.

The first volume of the report on the triangulation of Prussia had scarcely been published when it was attacked on all sides. It comprised the triangles measured in the eastern portion of the kingdom. The first attack was made by Lieut.-General de Baeyer, the former collaborator of de Bessel, who repulsed with much vivacity a criticism made upon certain triangles of de Bissel, contained in the preface of the work in question; he showed, on the same occasion, that the results obtained were in all respects inferior to those of the ancient triangulation of de Bessel, and those of the triangulation of the coasts of Prussia. He stated that, in 1863, the Prussian Government had confided to M. de Baeyer the direction of the survey, and that at that period he had already disapproved of many things in the work which had been submitted to him. The Ordnance department took no notice of his protestations, and published the work in question without even informing M. de Baeyer, who was much surprised to find all the faults pointed out by him, and as many others as they had time to add. He has hastened to disavow this publication in a letter addressed to the *Astronomische Nachrichten*. Lieutenant-Colonel de Hesse, Chief of the Ordnance Department, replied, and undertakes to justify himself, but M. Peters has taken part himself against the department. Moreover, M. Wittstein, Professor of Mathematics at Hanover, has published two articles successively in the same journal, in which he endeavours to prove that the Department of Triangulation does not know what a personal error is, and that it does not know how to *compose* the bearings observed at the same station. M. Wittstein concludes that all the calculations of the triangulation must be made over again.

M. Pisko, professor of physics at the Lyceum of Wieden, at Vienna, has related to us a curious accident which he witnessed, and which is highly interesting to physiologists. The servant of the laboratory of the Lyceum is an old corporal of the *gendarmes*, of a strong constitution and always in excellent health. In the month of February last year he was occupied in cleaning an induction apparatus, and he conceived the idea of trying it with several elements. When he had laid hold of the two handles he could not let them go. Fearing that his imprudence should be discovered he would not cry out for help though he was groaning with pain. He remained in this situation for more than ten minutes, and we cannot tell what would have happened if he had not fallen to the ground and in his fall broken the conducting wire. After some time he recovered the use of his limbs and continued his usual occupation. The following day he felt some uncomfortable and strange symptoms; when walking he fancied everything he walked upon was spherical. The next day, about 11 o'clock, these sensations became stronger, both his arms were swelled from the elbow to the fingers, and the legs from the knee to the extremity of the toes; the patient had to keep his bed. When he tried to get up it seemed as if he could not touch the ground, the swelling and the pain attaining its maximum about 2 o'clock and disappearing about 4 o'clock. A doctor was called in, but the man at first concealed the nature of his malady; he said he had stirred the acid of the battery with his hand. Warm baths ordered by the doctor produced no effect. It was only on the fifth day that M. Pisko, absent till then, was informed of the state of his assistant. M. Pisko went to see him, and on his saying he did not believe the story of the acid, the man confessed what had happened. The Professor then proposed to the doctor who attended the patient to use the same remedy as that applied in cases of lightning stroke, viz., quinine and old wine. This treatment turned out to be efficacious, and by the end of fifteen days the periodical symptoms had gradually disappeared, without leaving a trace. Nevertheless, in the month of February last, just a year after the accident, the same symptoms were renewed, though with less intensity. Treated with the same remedy as before they yielded at the end of eight days. It will be curious to see if the symptoms return in February, 1868.

The Imperial School of Pharmacie has just lost one of its most experienced savants, in the person of M. Guibourt, honorary professor. He was born in Paris, in 1790, and was, at sixteen years old, on the termination of his classical studies, apprenticed to the Boûdet pharmacy. He was author of several pharmaceutical works of the highest merit. By these and his constant studies he acquired, justly, the name of being the most distinguished savant in medical and pharmaceutical materia. Named Member of the Academy of Medicine in 1824, and Professor of the School of Pharmacy in 1832, he was also received into many national and foreign learned societies.

Anti-incrustator for Steam Boilers.—Gifford's Monster Balloon. —Prize Subjects of the Haarlem Society of Sciences.—Fluorine Compounds, Isolation of Fluorine.—Potato Disease. —Preservation of Anatomical Specimens.—Report on Unity of Weights and Measures.

M. E. Schmitz exhibits an anti-incrustator for a steam boiler, composed of small surfaced curved blades, placed in contact one with the other in the same manner as curved tiles on the ridge of a house roof, in such a way that their *ensemble* forms a sort of double bottom in the boiler and in the generators. This double bottom only leaves a thin layer of water, of unequal thickness, absorbing the caloric, in consequence, under unequal conditions. The result is that the liquid particles are put rapidly in motion according to the difference of densities produced by the heat. The direction of the motion is transversal, and the circulation is caused to move upwards; on one side the steam, as soon as it is formed, while on the opposite side the water, less hot, descends to be vaporized in its turn. This circulation, which is very rapid and continuous, produces effects which annihilate completely the two causes of destruction.

The velocity of the liquid current is propagated throughout its entire mass, and determines a sort of molecular rolling which tends to take up the heat transmitted by the heated surface of the boiler, as quickly as it is formed. The liquid mass thus becomes the regulator of the heating of the metallic envelope which contains it, and, consequently, diminishes the causes of unequal dilations. By its rapidity, the current does not allow any matter to adhere to the surface of the boiler, and carries all impurities to the surface of the water, where the steam is separated without perturbation. Thus the deposit takes place on the inner surface of the double bottom, and as there is always a current of water in contact with the bottom of the boiler, it can never get red hot. By the anti-incrustator of M. Schmidt the risk of explosion is considerably reduced.

The great news of the day is the inauguration on the 7th inst. of the anchored balloon of M. Henry Giffard, the celebrated inventor of the injector for steam engines. He has spent more than £4,000 upon the realisation of the greatest experiment of modern times. Having rented a plot of ground adjoining the extensive engine factory and machine works of M. Henry Flaud, he has erected an immense cylindrical screen of canvas fixed upon vertical poles. In this he has constructed a balloon 69 feet in diameter, holding 210,000 cubic feet of gas, formed of two webs of closely woven linen, cemented together by several layers of American black india-rubber varnish, the whole being covered with drying oil so as to prevent any of the effects of osmose or diffusion. Two series of gigantic apparatus have been constructed on the same spot, for the production of pure hydrogen. The first is composed of 100 barrels, each containing 155lbs. of dilute sulphuric acid, with a large quantity of iron turnings capable of furnishing, each, 350 to 400 cubic metres of gas. The second apparatus is a steam generator, by aid of which the steam is decomposed,

[English Edition, Vol. XVI., No. 406, page 134, and No. 407, pages 153, 154.]

by passing over red-hot charcoal or incandescent coke, into pure hydrogen and carbonic acid gas; the hydrogen is separated from the mixture by the aid of quick lime, which absorbs the carbonic acid gas and leaves the hydrogen pure, dry, and cool, to be conducted by a main pipe to the upper part of the balloon. With this second series the hydrogen only costs two-pence per mètre cube (or about 4s. 9d. per 1,000ft.), but the preparations are not quite completed; in a trial on the 9th inst. the balloon was inflated with hydrogen resulting from the action of the sulphuric acid, and the operation was finished in 8 hours, whereas the filling of the balloon with gas procured by the decomposition of water took 48 hours. The former process gave also 3,500 cubic feet of mother-water of sulphate of iron, collected in a vast subterranean basin, which can be sold to be evaporated by chemical manufacturers, and which are sufficient to disinfect the cesspools of a whole quarter of Paris. Inflated on Saturday, the balloon had lost almost nothing of its gas on Monday, and on Thursday the 12th, when we visited it, the total loss of hydrogen was only 2,100 cubic feet, or a hundredth part of the total volume of gas with which the balloon had been inflated. The osmose or the diffusion is really prevented. The closing of the upper and lower valves, ingenious beyond description, is absolutely hermetical. We need scarcely remind our readers that the cable, 984 feet long, by which the balloon is attached to the earth, is coiled and uncoiled by two different steam engines, which the mechanician can stop or set at work at will by means of cocks which serve for the distribution of the steam.

The inflation being terminated, the balloon, containing 210,000 cubic feet of hydrogen gas, was retained by the ballast; at each of the 70 ropes of the group were attached ten sand bags weighing each 33lbs.; and in spite of this weight of 22,100lbs. the car was more than 3 feet from the ground, so great was the ascensional force. A rather strong wind, that may be estimated at 33 feet per second, was then blowing, but it did not prevent the balloon from rising in a vertical direction. These experiments, suspended for some days, were to have been renewed on Saturday last. This organisation of a view of Paris from a height of 984 feet reflects great credit on M. Giffard.

The Dutch Society of Sciences of Haarlem proposes for public competition the following subjects, the essays on which are to be deposited before the 1st January, 1869:—1. Profound researches on the nature of the infecting principle of the contagious typhus of cattle, indicating at the same time the prophylactic methods, the employment of which proceeds rationally from the result of these investigations. On account of the great importance attached to the solution of this first question by the Society, an extraordinary premium of five hundred florins will be added to the gold medal. 2. Detailed examination of the different substances composing the liquid produce of the dry distillation of coal. 3. The experiments of Mr. Tyndall have demonstrated that the intensity of sound differs considerably according as it is propagated in hydrogen or in atmospheric air, even when the densities of the two gases are equal; the Society demands, on this subject, comparative experiments made with at least three different simple gases. 4. To decide experimentally if the radicular extremities of plants exude matters capable of dissolving the silicic acid which is found in the ground in the shape of quartz. 5. New researches on the mutual decomposition of saline solutions containing different bases and acids which decide between the doctrine of affinities and that of Bergmann. 6. Ulterior exact researches on the remarkable phenomena of dissociation discovered by M. Sainte-Claire-Deville.

The chemical event of the last month has been the forwarding by M. Dumas, to the Academy of Sciences, of the researches of Mr. Prat on the chemical constitution of fluorine compounds and the separation of the fluorine. Mr. Prat started from this fact that the fluorides are really oxyfluorides; that the fluoride of calcium, for example, is formed of two equivalents of calcium, one of oxygen, one of fluorine, and that, in consequence, the true equivalent of fluorine is 29·5, and not 19, and that, in order to obtain it, all that is necessary is to treat the fluoride of calcium with chlorate of potassium, or, what is better, perchlorate of potassium, for it is only with this last salt that the reaction takes place. Oxygen is disengaged and a gas is produced which silver absorbs, giving rise to a fluoride of silver, insoluble in water, soluble in ammonia, from which it is precipitated by nitric acid, and which is altered by the action of light more rapidly than the chloride of silver; the formula of the real chloride is $AgFl$, whilst that of the soluble fluoride of chemists is $AgFl,AgO$. Fluorine is obtained by heating, in a platinum retort, fluoride of lead of the chemists one part, either with nitre five parts, or with binoxide of manganese two parts. Oxygen gas and fluorine are disengaged, the oxygen is taken up in its passage by fragments of heated baryta. Fluorine is gaseous, nearly colourless, possessing an odour like chlorine, very visibly giving off fumes in the air, incombustible, and heavier than air; it dissolves indigo, reddens and discolours litmus paper, disengages fumes in contact with ammonia, decomposes water at the ordinary temperature, combines with hydrogen under the influence of diffused light, and eliminates bromine and iodine from their compounds; it unites with boron, silicium, and all the metals of the first five groups.

MM. Juette and Ponteves have succeeded in preparing tartaric acid from the skins of grapes, after they have been pressed and distilled, and can be put to no use but as manure. After distillation the skins are treated with water so as to obtain lees, to which is added 2 per cent. of sulphuric acid, and the mixture is boiled for some hours. The tartaric acid in combination is set at liberty, and, moreover, not only the sugar escaped from the fermentation is not eliminated, but the action of the sulphuric acid on the cellulose of the pulp of the grape forms a certain quantity of glucose. The liquor is allowed to ferment, and a supplementary distillation gives again an appreciable quantity of alcohol. When the decantation has been made, lime-wash is added, and tartrate of lime is produced, from which the tartaric acid is extracted by the ordinary method. According to the inventors the quantity of grape skins left after 1 million hectolitres of wine, treated by this process, would give 200,000 kilogrammes of tartaric acid the value of which is about 600,000 francs. (£24,000)

The Marquis of Havrincourt has addressed to the *Courier de Pas de Calais* the following letter: "M. Georges Ville, by following his very ingenious method of examining the vegetation of plants themselves, has just discovered the cause of the potato disease. The cryptogamia are the result and not the cause of the malady. Let any one go to the experimental grounds of Vincennes and he will be convinced as I have been. He will see there a plot of potatoes divided into five parts touching each other: the first is luxuriant and has not a sick leaf, the second is attacked by the malady; the third is as the first; the fourth is as diseased as the second; and the fifth resembles the first and third. Thus M. Georges Ville produces or avoids the potato disease at will."

The following is the process of M. Von Vetter for the preservation of anatomical specimens:—Add to 7 parts of glycerine at 22° one part of raw brown sugar, and half a part of nitre till a slight deposit is formed at the bottom of the vessel. The portion required to be preserved is then plunged, dried or not dried, and it is left in the mixture for a time proportional to its dimensions; a hand, for example, should remain eight days in the liquid; when it is taken out it is as stiff as a piece of wood, but if it be suspended in a dry and warm place the muscles and articulation recover their suppleness.

M. Jacobi has just issued his report on the Unity of Weights and Measures, drawn up in the name of the Commission of Moneys, etc., of the Exhibition.

On summing up, the commission think that the governments ought to keep the following objects in view:—The substitution, as soon as possible, but integrally, of the metric system as is practised in the west of Europe and in many other countries, in place of the old systems of weights and measures. This system introduced at once, and rendered legal but optional, cannot be rendered obligatory at first. The period of toleration varies with the state of the different people, their degree of instruction, etc., and it can only be determined by the governments. It has been remarked, however, that a too long delay does not perceptibly aid the governments in the accomplishment of their task. At all events, it is desirable that governments should take, henceforth, some necessary measures, which are—first, to order the study of the metric system in all schools, and to require a knowledge of it in public examinations; secondly, to introduce its exclusive use in scientific publications, public statistics, in post-offices, custom-houses, public works, and any other branches of the administration that the governments may deem convenient. The commission does not consider that it is part of its mission to occupy itself with the making of standards, exact copies of the prototypes of Paris, the possession of which, in a practical point of view, is the indispensable preliminary of every metrical reform. The administration of each country will appreciate the degree of exactitude suitable to the different destinations of these standards.

REPORTS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

MICROSCOPICAL AND NATURAL HISTORY SECTION.

July 18th, 1867.

J. B. Dancer, *F.R.A.S.*, *President of the Section, in the Chair.*

"*Some Further Observations on the Cause of Rotation in the Cells of Vallisneria,*" by James G. Lynde, F.G.S., F.R.M.S.

In a paper read by me at a meeting of the Section on the 16th February, 1863, "On the Action of Magenta Dye upon Vegetable Tissue," I described a series of experiments upon cuttings of Vallisneria, made chiefly with a view to ascertain, if possible, the cause of the rotation of the chlorophyl vesicles within the cells.

I then concluded that the rotation was due to the action of cilia on the inner surface of the cell wall, and was confirmed in this opinion not only by the appearance of the luminous stratum or so-called ciliary wave which had been observed by Dr. Branson, Mr. Wenham, and others, but also by the appearance on the cell walls of certain markings revealed by the action of the dye on the suspension of the vital action.

The above experiment was exhibited to the Section, and many of the members present attributed these markings, as I had done, to the presence of cilia.

I have since, from time to time, pursued my experiments on the subject, in the hope that I might be able to adduce more positive evidence as to the cause of the wave of light on the interior of the cell wall.

After many fruitless experiments I at length determined to try the effect of polarized light, and on the application of it with a ⅛th-inch objective, having an aperture of 130° to 162°, and so arranging Darker's series of selenite plates as to give a dark blue ground, there appeared over the surface of the surface of all the cells brilliant gold-coloured scintillations which had all the appearance of cilia in motion.

The portion of leaf under examination exhibited very sluggish circulation, and was therefore in a very favourable state for the observation.

I have since repeated the experiment several times, and have never failed witnessing the same appearance.

Notwithstanding all that I have seen I cannot say that I am convinced the appearances can be attributed to nothing else but cilia; it is possible they may be due to the presence of active corpuscles, as suggested by Mr. Wenham in his paper on the leaf cells of Anacharis alsinastrum published in the *Microscopical Journal* for 1855, which corpuscles may be Vibrionia or Zooglæ, described by Dr. Cohn in his "Researches on the Development of the Microscopic Algæ and Fungi," as representing the developmental condition of a plant, but it is only by further research that this point can be definitely settled.

The result of my observations so far appears to be that in addition to the wave of light already seen, the separate objects causing that wave may now be observed in the manner I describe; what these objects are is still a matter to be determined, but at present I am inclined to believe them to be cilia on the cell wall, while at the same time there are also independent moving corpuscles within the cell; some of these bodies have the appearance of crystals, and in one specimen I observed a great number of starch granules in the cells.

In investigating this subject the smallest step in advance cannot but be deemed of importance, and I trust that in giving the results of my observations as they occur, I may be the means of saving time and trouble to others who may be investigating the same class of objects, and of inducing them to follow up so interesting a subject, as it is only by many and independent observations the truth can be ascertained.

For the information of members I may state in detail the method of observation I have found most successful.

The microscope I made use of is one of Smith and Beck's largest size, binocular, with one of Beck's most recent ⅛th-inch objectives.

The illumination was by means of an Argand gas burner, the light passing into a right-angled prism below the stage in a line with the axis of the object glass.

Immediately beneath the stage was the achromatic condenser, used both with and without the central stop in the diaphragm, the object being seen equally well in both ways with different effects of light.

Below the achromatic condenser was fixed Darker's series of selenites, and below this the polarizing prism, the analysing prism being inserted immediately above the objective.

I made use of the low Huyghenian eye-pieces and used the microscope either as a binocular or single tube, the field being well illuminated in each case.

I need not add that the most careful centering and adjustment are essential.

In preparing the object I made a section of a small portion of the leaf laid on a piece of cork in water under a simple microscope, separating only one layer of cells; I laid this on a slip made of thin covering glass, and over it applied a thin glass cover, a small feeding bottle and thread being made use of to prevent the object being dried by evaporation.

I then covered the stage and object with a piece of black velvet, to prevent interference from other lights in the room.

BRITISH MEDICAL ASSOCIATION.

Twenty-Fifth Annual Meeting, 1867, *held in Dublin.*

In a paper entitled, "*Mode of Detecting Impurities in Tetrachloride of Carbon,*" read in the Midwifery Section, Dr. Protheroe Smith observed, that previous to the publication of his account of this anæsthetic in the numbers of the *Lancet* of last June, there were few if any pure specimens of the tetrachloride to be obtained. To this circumstance he attributes the contradictory conclusions which in some instances had been arrived at by those who had experimented with the tetrachloride. After studying concisely its physical and chemical properties, Dr. Protheroe Smith remarked that the chief cause of the failures above mentioned were the three following impurities:—

I. *Bisulphide of Carbon.*—This is easily detected by evaporating over a spirit-lamp a portion of the suspected fluid in a deep cup, when, if it contains bisulphide, a slightly bluish flame will appear, whereas if free from this impurity it would be entirely uninflammable.

II. *Free Sulphur.*—Should such exist, after spontaneous evaporation of some of the tetrachloride on a watch-glass, a fine opaque film will remain, which when heated would give off the well-known fumes of sulphurous acid.

III. A peculiar sulphur-compound, which is discovered by dipping in the suspected fluid some clean blotting-paper, which when dry will give a peculiar unpleasant smell of dirty linen.

Dr. Protheroe Smith also exhibited his inhaler. It consists of a graduated glass receiver for the anæsthetic, with a tube in its centre, by which at every inspiration air passes first through the fluid, and then through the sponge, thus becoming so highly charged with its vapour as very rapidly to induce anæsthesia.

This mode of administering anæsthetics effects a salvage of from $\frac{3}{4}$ to $\frac{7}{8}$ of the fluid, so that a drachm may go as far as an ounce when employed as ordinarily on a handkerchief. Dr. Protheroe Smith entered more fully into the comparative merits of tetrachloride of carbon and chloroform in an animated discussion on the action of anæsthetics which took place in the Midwifery Section on Friday afternoon, when Sir James Simpson called upon him to give his experience. Some of the advantages claimed for tetrachloride of carbon were that its administration is rarely followed by sickness or other derangement of health,—that it does not seem to interrupt the natural efforts of labour as often observant with chloroform,—that its effect upon the perceptive faculties very rapidly ceases,—that it can be made at much less cost than any other anæsthetic,—that a smaller quantity suffices for use, and for many other medical reasons which were given.

Dr. Smith's tetrachloride is evidently made by passing the vapour of bisulphide of carbon and chlorine through a red-hot tube. There is no doubt that this compound can be procured very cheaply by this method, and that ultimately it will be used in the arts; much of the so-called tetrachloride, however, now met with is procured by the action of chlorine upon chloroform, and is frequently a mixture of chloroform, other chlorides of carbon, and the tetrachloride.

ACADEMY OF SCIENCES.

Aug. 20, 1867.

(From our own Correspondent).

Shooting Stars.—Animal Electricity.—The Pascal-Newton Forgeries.—Photographic Registration of the Beatings of the Heart.

The correspondence was without interest.

M. Coste presented, on the part of MM. Coulvier-Gravier and Chapelas, the result of their observations on the shooting stars during the nights of the 9th, 10th, and 11th of August of this year. They showed, by a tabular statement, that from the 5th of August, the mean hourly number at midnight on a clear sky, that is to say, corrected for the lunar light and the presence of clouds, was 16·2 stars; this became 33·7 on the 9th, 49·9 on the 10th, and 28·7 on the 11th; giving an average of 37·4. Comparing this with the year 1848, which had given for the mean hourly number, 110 meteors, it is plain that the quantity diminishes very sensibly.

M. Saigey, formerly collaborator of M. Coulvier-Gravier, has just published the results of his meteoric observations made in 1845 and 1849 for all the clear nights.

M. Schultzstein, of Berlin, read a paper on animal electricity, stating that all the phenomena are reduced to simple voltaic currents in which salt acts the part of the electromotor.

M. Chasles took up the discussion relative to Pascal's and Newton's letters. He is astonished that their authenticity has been doubted, inasmuch as they are exchanged between twelve different persons. The writing of Montesquieu is well known; and there are letters from Marriotte, whose writing can be compared with that of manuscripts in the library, etc. There are about 500 letters and notes of Pascal, 200 of Newton, and 300 of Labruyère in the possession of Pascal.

M. Le Verrier declared his incompetence as a member of the commission to inquire into the documents of M. Chasles, and regretted that he could not assist this gentleman in any way in the absence of proofs; and in polite terms demanded the usual proofs of authenticity required by astronomers, so that they could judge when they received them.

M. Chasles replied in warm terms, and a rather stormy discussion ensued. He said that the number and nature of the documents communicated ought to satisfy all doubts as to their authenticity! He added that he was going to publish the most curious letters — for example, those of Molière to Rotrou, and Rotrou to Pocquelin, poetry, unpublished, and other pieces by Rotrou, also letters, etc., from Corneille to Rotrou.

M. Chevreul stated to M. Le Verrier his acknowledgment of the inutility of a commission appointed with too much precipitation.

M. De Landolle proposed in the name of several foreign botanists a change in the nomenclature of botanical classification.

M. Ozonam presented a note on an apparatus by which the beatings of the heart are registered and photographed. They are made to act on the surface of a bent tube containing mercury, the fluctuations of which are noted in the same manner as those of the thermometer and barometer are photographed. He exhibited several curves obtained by this means, and some magnified by the megascope.

Aug. 26, 1867.

Death of Dr. Velpeau.—Fluorine.—M. Chasles' Manuscripts.

A gloom was cast over the assembly by the death of the celebrated Dr. Velpeau, born on 18th May, 1785, at the village of La Briche, in Touraine. The son of a blacksmith and farrier, whom he aided in his trade, he became acquainted with the first notions of veterinary surgery. In 1816 we find him at Tours, a medical student; and in 1820 at Paris, where he was made doctor three years later. Laborious and tenacious, he rapidly amassed money, especially as his private practice was confined to the higher aristocracy. As hospital surgeon of the Pitié, as professor, as academician, he led the example of punctuality, assiduity, and practical skill in conducting operations, so that he became at once one of the best surgeons of France. In 1842 he was elected to the vacant chair at the Institute, having been previously, in 1835, nominated, though he had for a fellow competitor the celebrated Lisfranc. His titles were: Surgeon to the Charité, Member of the Institute, and of the Academy of Medicine, Commander of the Legion of Honour, Professor of Medicine, and Consulting Surgeon to the Emperor. The numerous works written by him are not so easily enumerated; we have before us the list of 18, most of which are in several volumes and accompanied with atlases and magnificent engravings; without counting all the valuable papers read at various societies, they prove that he wielded the pen as steadily as the bistoury, or the hammer on the anvil, in his early days.

Surgical and medical science have lost latterly many in their front ranks; Malgaigne, Jobert, Civiale, Trousseau, Charrière, and last, Velpeau. Funeral discourses were pronounced by Nelaton, Riche, Gosselin, Husson, Guyon, and Longett; the latter was pupil and friend of the deceased.

Among the correspondence, which was opened by M. Chevreul, was an important one on fluorine, by M. Pratt. According to this chemist we have been hitherto mistaken upon the composition of fluorides, and on the theory of fluorine. M. Pratt proposes new formulæ, which harmonise better with known analyses. These will be examined in detail when the *Comptes Rendus* appear.

M. Balard presented a note on chloride of ethylene.

M. Blanchard reminded the assembly that at the last meetings of the Academy doubts were expressed upon the existence of unpublished manuscripts of Pascal, which would contain important discoveries. He thinks that these doubts ought to be satisfied by a declaration contained in a passage of the preface of the "Treatise on the Equilibrium of Heavy Liquids," published in French. M. Blanchard states that this preface was probably written by Madame Perier. The edition in the hands of M. Blanchard is dated 1698, and is conformable to those of 1663 and 1664.

M. Faugère having been invited by the president to state his objections against the authenticity of the documents published by M. Chasles, stated that the falsificator had not even well *imitated* the handwriting of Pascal. He said that the forger was merely satisfied in adopting the writing and style of language of the 17th century.

M. Faugère confined his observations to mentioning an anachronism, according to him, most evident. There is a question, in one of the letters, on the froth of coffee; now, the use of coffee was not introduced into France before the end of the year 1669. He contested that Newton never wrote in French, also he remarked upon the common-place style of the letters attributed to Pascal, whose diction was far different, and added that the forger was caught in his own net. He hoped that the imposition upon M. Chasles would be shortly cleared up.

M. Chasles replied that all these doubts have not shaken his confidence in the authenticity of his documents, so numerous and varied.

M. Regnault observed that photography would furnish the means of recognising whether the old papers contained anterior writing that may have been made to disappear. Also there are chemical reagents calculated to revive effaced writing.

M. Chasles declared that he would place at the disposition of the Academy all the letters and documents to be submitted to all manner of tests.

M. d'Abbadie presented on the part of M. Radau a note on the ancient meteorograph and on the theory of the barometer of M. Moreland. We find in the *Journal de Physique* of the Abbè Rozier (1782), a memoir of Magellan, giving a description, accompanied with plates, of a "Perpetual Meteorograph." Seven instruments trace parallel curves on the same diagram, moved by clockwork. The pressure is registered by a wheel barometer, the temperature by a metallic thermometer, and the humidity by a hygroscope constructed of wood; the force and direction of the winds are obtained by a very ingenious anemograph; rain, evaporation and the height of the tides are indicated by apparatus furnished with floats. Nothing is wanting, and in several respects this meteorograph is superior to those recently constructed. The steel yard barometer was invented by Sir Samuel Morland, who presented it towards 1670 to Charles II. Magellan possessed a barometer on this principle, constructed by Jonathan Sisson; he improved the mode of suspension. Later, in 1791, the Rev. Arthur M'Quire le transforma en barographe en attachant un crayon au sourmet du tube (*Transactions* of the Royal Irish Academy, Vol. IV.). The theory of the barometer, complicated enough, was not as yet given exactly.

Sept. 2, 1867.

Death of Faraday.—Godard and Savigny Prizes; Father Secchi on Shooting Stars.—Stellar Spectroscope.

A letter from Mr. Dumas informed the Academy of the loss it has just sustained by the death of Mr. Faraday, one of its foreign associates. M. Dumas made this mournful communication at the request of M. Tyndall, who thought that M. Dumas could, as one of the friends of the illustrious deceased, replace, in the performance of this duty, his family.

M. Chevreul, after having read this letter, added that all the members of the Academy would certainly participate in the sentiments it expressed; he paid a solemn homage to the memory of the great English physicist, and related several facts which manifested his modesty, and the nobleness of his character.

The correspondence included some documents on the definitive disappearance of the great birds of Madagascar (Epiornis Maximus), and on the work of MM. Burden and Bourget, on heat, etc.

M. Chasles replied to the criticisms of M. Faugère. He commenced by enumerating again the very important and varied documents in his possession, among which are about 1,000 documents of La Bruyère (nearly 300 letters, a key of characters, the same which circulated at that time among the intimate friends of La Bruyère, and many other isolated pieces). M. Chasles combated, one by one, the objections raised by M. Faugère, apparently successfully. He remarked how very improbable it was that a falsificator could fabricate such an immense number of documents of a nature so different. He must have had a great imagination!

M. Chasles cited letters from Desmaizeaux to Fontenelle, in which there is doubt of the relations between Newton and Pascal; they say it was the professor of young Newton who wrote his letters. M. Bertrand remarked how singular it was that no allusion is made to this in Fontenelle's *eloge* of Newton. M. Chasles replied that Fontenelle had requested of Desmaizeaux information as to the youth of Newton before he wrote his discourse. Desmaizeaux, in his reply, said that he possessed Newton's papers, but that his family had confided them to him on the condition of not making use of them. "I will give you," he said, "notes, but which will not injure the reputation of M. Newton, so well established." Fontenelle submitted to Desmaizeaux his project of *eloge*, and the latter prayed him not to revive old souvenirs nearly forgotten. Leibnitz knew all these things; he avowed that he had papers of Pascal, *but that he makes no mystery of them, like M. Newton.*

A commission was appointed for the Godard prize, and another for the Savigny prize, founded by Mademoiselle Lettellier, in favour of young travelling zoologists.

Father Secchi made several interesting communications. The first was on shooting stars. The cholera had dispersed the small staff of assistants at his disposal at Rome; nevertheless, he had two observers who determined that on the 10th of November the hourly number was thirty-five between two and three in the morning. Comparing this number with that observed in the previous year, it appears that at Rome the diminution was not so sensible as at other places. He then presented a stellar spectroscope, of very moderate dimensions, made by Secretan; also a memoir on the actual state of the science of meteorology as regards metorographic instruments, and laid upon the table sheets on which the meteorograph of the Exhibition had traced curves.

M. Archiac presented several memoirs relative to geology.

Sept. 9, 1867.

The Pascal-Newton Forgeries.—New Compounds of Cyanide of Amyl.—Polarisation of Electrodes.

Let me say a few words on the answers of M. Chasles to the objections urged by M. Faugère, which had some appearance of gravity. The first was the allusion made in one of the letters written by Pascal, in 1652, about coffee and the froth of coffee. "Coffee," he said, "was not introduced into Parisian society before 1660, about seven years after the death of Pascal." Thus, without going further, M. Chasles finds in the Dictionary of Bouillet that coffee was drank in Venice in 1615, and at Marseilles in 1654; and in the new curious treatises on coffee, tea, and chocolate, published by Philip Sylvester Dufour, in 1684, we find "coffee has not been known in France for more than forty years." Subtracting these forty from 1684 we have 1644. Pascal, young, well acquainted with the world, and ardent in the advancement of progress, would not have been the last to have known the existence of coffee. Moreover, a forger, while treating on universal gravitation, would not have dreamt of connecting it with the froth of coffee.

To the second objection of the improbability of a correspondence between Pascal and Newton while children, as M. de Morgan and Sir David Brewster remark that he never knew French otherwise than with a dictionary, M. Chasles answers by presenting striking documents.

"PASCAL TO WALLIS.

"This 29th August, *apropos* of this young student (Newton), can you give me some tidings of him, and principally about his arrangements. Some friends assured me that the letters written by him to me, and the questions that he has submitted seem to have rather come from his professor than from him. I should like very much to have correct information. Perhaps you can give me a word about it? I am waiting for your reply."

"DESMAIZEAUX TO FONTENELLE.

"October 20, 1727.—This one (the Professor) advised his young pupil to write a letter to Pascal, and to submit to him some geometric questions or problems to be solved. It is the best way, said he, to obtain an answer. The letter was then prepared in concert with the Professor, as well as the questions, and sent by young Newton, yet a student, to M. Pascal. The latter finding, without doubt, the letter and questions extraordinary for a child, and recollecting, perhaps, that he himself had been a precocious child, ardent to learn, searching everywhere to instruct himself, replied to the young Newton. It was thus that relations sprang up between the two men of genius, which lasted till the death of Pascal. I am perfectly sure that young Newton took part in it. It could not be otherwise. However, 'M. Le Chevalier Newton' has avowed it to me himself, that it was these relations which engaged him to follow a scientific career."

Little satisfied with the peremptory answers of M. Chasles, M. Faugère returned to the charge and answered one by one his arguments without signification, insisting, above all, on the verification of the writing. Now, M. Chasles declared that he is ready to accompany him to the Imperial Library, in presence of the members of the Commission and the Academy who would wish to take part in it.

At the last meeting M. Dumas transmitted a second letter from Dr. A. W. Hofmann on a new compound of cyanide of amyl analogous to hydrocyanic acid. By pouring gradually a mixture of an alcoholic solution of ethylamine and chloroform into a retort containing pulverised hydrate of potash, a most energetic reaction takes place; the mixture becomes heated to the boiling point, and a liquid distils over, the penetrating odour of which surpasses all that can possibly be imagined. The liquid is the cyanide of amyl, transparent, colourless, lighter than water, insoluble in water, soluble in alcohol and ether, possessing an insufferable odour something like that of amylaceous alcohol and hydrocyanic acid. Its vapour possesses, in a higher degree than that of cyanide of phenyl, the property of leaving an intensely bitter taste on the tongue, and a suffocating feeling in the throat similar to that produced by prussic acid. It can be distilled without decomposition, and boils at 137°C. But little attacked by alkalies, it is decomposed by acids, with an almost explosive violence; a slight ebullition in presence of acidulated water is sufficient to transform it into formic acid and amylamen.

$$\underset{\text{Cyanide of amyl.}}{C_6H_{11}N} + 2H_2O = \underset{\text{Formic acid.}}{CH_2O_2} + \underset{\text{Amylamen.}}{C_5H_{13}N}$$

At present M. Balard, by virtue of a note inserted in the *Comptes Rendus*, and the *Treatise on Chemistry*, of M. Naquet, claims the discovery of this new analogue of cyanhydric acid in favour of M. Armand Gauthier, laboratory pupil of M. Wurtz.

M. Gaugain presented a note on the polarisation of electrodes. Several savants have sought to determine the part which each of the electrodes takes in the polarisation, and have arrived at different results: M. Poggendorff found that the two electrodes contributed equally to the production of the electromotive force developed; MM. Lenz and Sawelgew found on the contrary that the part of the cathode is greater than that of the anode. M. Gaugain tried in his turn to resolve the question by making use, as he did on former occasions, of the *method of opposition*, and the following are the dispositions he adopted. In a cylindrical glass vase he placed a porous cylinder of much smaller diameter, and both vessels were filled with the same liquid. The strips of platinum which are to serve for the decomposition of the liquid are placed in the exterior vase, and a third plate of metal is introduced into the porous cylinder; this third plate, which remains constantly out of the circuit, traversed by the current, does not experience any polarisation, and can be successively compared with each of the electrodes when these are polarised to saturation; this comparison gives the measure of the two polarisations of the anode and the cathode. The porous diaphragm serves to keep the neutral plate out of reach of the influence of the hydrogen disengaged by the electrolysis.

The following are the results thus obtained by a series of experiments carried on with a mixture of nine parts by volume of distilled water, and one part of sulphuric acid.

Polarisation of the anode...........	193
" " cathode.........	157
Total polarisation.................	352

It appears to be of little consequence, if more or less sulphuric acid be added to the electrolysed water, provided that this proportion does not fall below a certain limit; but when it becomes extremely small the polarisation of the cathode increases without the polarisation of the anode being sensibly modified. The following are the results obtained by electrolysing pure water:—

Polarisation of the anode............	193
" " cathode..........	243
Total polarisation..................	434

M. Matteucci recently (*Comptes Rendus*, Jan. 14, 1867) called the attention of the Academy to an experiment which he had made in 1838, and upon which he depended to prove that the polarisation proceeded from the gases adherent to the electrodes. In fact, polarised metals should be considered as fugitive combinations formed by the metals and gases, and the author is of opinion that in couples of polarisation as well as in Grove's gas pile, the electromotive force is the affinity exerted on one of the elements of the water by a gas associated in a particular manner to a metal.

BRITISH PHARMACEUTICAL CONFERENCE.

Fourth Annual Meeting at Dundee. President, PROFESSOR BENTLEY, F.L.S., M.R.C.S., etc.

THE President opened the proceedings on Tuesday, Sept. 3, by delivering a most interesting address on "the study of botany in connection with pharmacy." Last year he gave an address on the same subject, when he confined himself to the consideration of some of the more immediate and direct advantages which the pharmaceutist would derive from a knowledge of botany, while this year he spoke of its value as a mental training, and as a recreation. Having alluded to the great advantages to be derived from the study of such branches of natural history as botany, in training the mind to observe correctly, discriminate accurately, and to acquire orderly and systematic habits, the president expressed a hope that it would not be long before such studies will become an essential part of the education of our youth. He then spoke of the advantage which the pharmaceutist would derive from taking up the study of a natural science by the combination of scientific with the more purely practical studies of their profession, thanking the liberal and enlightened founders and subsequent supporters of the Pharmaceutical Society for doing much to drive away the erroneous idea that a pharmaceutist should confine his attention entirely to the practical parts of his business. The president then proved the study of botany to be eminently calculated to prove an agreeable and healthful recreation to the pharmaceutist, urging upon the young student of pharmacy, the importance of its study during his pupilage in order that he may acquire that knowledge of its details and technicalities, as will enable him hereafter to pursue and enjoy it as a recreation, and concluded by thanking the local committee for the kind hospitable manner in which they received the visitors and for the very satisfactory arrangements they had made for holding the meetings of the conference.

We subjoin abstracts of the papers read during the sittings.

"*On the Adulteration of White Precipitate.*" By J. B. Barnes, F.C.S.

Seventeen years ago I tested some white precipitate, in the stock of a highly respectable pharmaceutist, and found it contained 50 per cent. of chalk, it had been supplied by a large wholesale house, at the price of a pure article..

I have received from members of the Conference, residing in the principal towns, 58 samples, and three other specimens —small portions of each of these parcels were separately exposed to the action of a strong heat. Of this large number (61) four only exhibited evidence of the adulterant; from Bristol, I received four specimens, No. 1, was pure; No. 2, contained 74·7 per cent. of carbonate of lead; No. 3, contained 22 per cent. of chalk, and No. 4, consisted entirely of carbonate of lead. From North Shields, three samples, one of them said to have been obtained by the retailer from Newcastle, and contained 94 per cent. of chalk. One sample from Shrewsbury contained a trace of peroxide of iron, the remaining samples were all pure—I venture to think the result is very creditable to the members of our profession, the samples having been obtained in neighbourhoods where it might have been supposed that adulterated samples would be met with; indeed, my Bristol contributor states that he obtained his specimens from a locality where he was sure to be able to find adulterated drugs.

"*Notes on Effervescing Citrate of Magnesia.*" By E. Dymond, *Birmingham.*

The author protests against the pleasing deception which is practised in the sale of the various popular granulated effervescing compounds, being almost without exception known by names which do not express their composition and real character, and he holds that the welfare of true pharmacy is in jeopardy whilst we tacitly recognize such departure from correct chemical nomenclature, and from those obligations which we are under to the pure truths of science and morality. The writer placed upon the table a specimen of saccharated effervescing citrate of magnesia which fulfils the conditions required in this preparation of brisk effervescence during the discharge of carbonic acid, and a nearly brihgt subsequent solution.

"*Remarks on a Specimen of Seaweed Char.*" By Ed. C. C. Stanford, F.C.S.

Mr. Stanford introduced to the meeting an interesting specimen of charcoal, obtained by the carbonization of tangle. This substance consists of the long stems of *Laminaria digitata*, which are thrown up in great abundance on the western shores of the outer Hebrides; these are collected in the winter and dried in the air: these, when first thrown up, are long fleshy stems, 7 to 8 feet in length, and about the thickness of the wrist, but when dried, present hard, horny, flexible rods, about the size of the finger. These, when carbonized, swell out into a highly porous charcoal, about three times their original volume.

The char contains about 40 per cent. of salts free from sulphides and very rich in iodine.

After lixiviation the residual char has the following composition; it varies slightly, and the average proximate analysis in the dry state, is here given:—

Carbon	50
Phosph. lime	4
Carbonate of lime	20
Carbonate of magnesia	6
Silicic acid	5
Alumina	2
Sulphate of potash	5
Chlor. iodine	5

and about 1·25 per cent. ammonia.

It generally contains about 15 per cent. of water, which it is very difficult to separate, the charcoal having a powerful affinity for moisture.

Attention was called to the remarkable analogy between the chemical composition of this char and that of animal charcoal, which appeared to class it with that substance, and render it unlike any other char of a vegetable origin. This char cannot be used for sugar refining, on account of the large percentage of carbonate of lime; but it possesses decolorizing and deodorizing properties, superior, weight for weight, to the best animal char; tested with solution of caramel it decolorizes 25 per cent. more than animal char under the same conditions.

It has been subjected to continued filtration of the thickest town sewage, for several months, without the least clogging, and its efficacy under this treatment remained unimpaired.

This communication was merely preliminary, the author promising the results of further investigation on this and other specimens of seaweed char.

The tangle char was brought before the meeting as a cheap and efficient substitute for animal char in its application other than that of sugar refining; and its introduction excited an interesting discussion.

"*On Glycelæum, a Proposed basis for Ointments.*" By T. B. Groves, F.C.S.

Take of

Almond meal	½ oz.
Glycerine	1 "
Olive oil	3 "

Mix s. a. It may be effected in a mortar in the ordinary way, up to nearly the end of the operation; but it is better, I think, to use the spatula and "slice" in the last addition of oil. It will then form a soft, semi-gelatinous paste, which, when mixed gradually with water or a watery fluid, forms readily an emulsion. The glycerine it contains being protected by the oil it does not quickly deliquesce, though when exposed to the air for some time it does often somewhat. It is of course unaffected by the ordinary temperatures of the body; if it were otherwise, its softness would be an objection to its use; as it is, it leaves plenty of room for powdery admixtures of every kind.

It is only essential to remember that the body in the first place must not precipitate emulsine, in the second place must be a fluid. I have in several ways attempted to emulse lard. I have melted it and succeeded perfectly, so long as it remained fluid; but if stirred after solidification, the emulsion was at once "inverted," or as Mr. Proctor styles it, converted into a "negative" emulsion, *i.e.* the glycerine is emulsed in the fat, and not the fat in the glycerine.

The advantages I attribute to glycelæum as compared with ointments and with plasma, I imagine to be these:—Ointments are greasy, prone to rancidity, do not "touch" in a strict sense, watery surfaces, and are not easily removed from the surfaces to which they become attached; on the other hand they are cheap, they are fatty, and they are repellent of moisture.

Glycelæum has been little tried as a remedy; I have had difficulty in finding persons to make a trial of it. Dr. Tilbury Fox has, however, at Mr. D. Hanbury's suggestion, made some experiments with it, and reports "that he likes it very much; that it is a capital thing where it is a desideratum to get hardened parts into a more 'supple' condition." Although I can bring but one testimony in its favour, it must be allowed to be a first-rate one.

Still less trial has been made of glycelæum as a vehicle for the administration of oils and balsams, though it would not be difficult to find stomachs that support with difficulty castor and cod-liver oils, and balsam of copaibæ. As "oiled" melted butter is known to upset a weak stomach, whilst well-made, *i.e.* well-emulsed melted butter does not, it might be inferred that an emulsed oil would in some cases agree with the stomach when the plain oil would not. I am convinced of this, that the glycelæum copaibæ, stiffened with powdered cubeb, would form a more elegant and a more supportable electuary than the nasty and imperfectly mixed mass one commonly meets with.

I have already alluded to the fact. that it is to the emulsine contained in the oil-seed we must attribute the extraordinary emulsive power of these emulsive powders. (Certainly no organic principle has been more consistently named than it.) This I have proved experimentally, by preparing some of the substance, and trying it in its pure state. I found that five grains dissolved in one drachm of water would emulse into a jelly four drachms of olive oil (using the spatula, not the pestle). I prepared the emulsine by digesting for a few hours powdered almond meal with tepid water filtered, and added to three measures of the filterate five measures of rectified spirit, collected the precipitate and dried it at a temperature not exceeding 100°.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

DUNDEE MEETING, 1867.

(From our Special Correspondent.)

Dundee, Sept. 5, 1867.

In spite of the great distance from London, and the depressing influence exerted by the parsimony of the railway companies, the present meeting promises to rival any of the previous northern gatherings, excepting, perhaps, the Newcastle meeting in 1863, at which the total number of attendants amounted to 3,335. At the time I write they are nearly equal to the total of the Nottingham meeting—2,300, and new arrivals are coming, both by rail and boat. The exigencies of the Post Office allow me only a very limited time to furnish this preliminary letter, so that if my narrative is imperfect in any material sense, I will communicate by telegraph, and the facts may then be interpolated by you. The lodging accommodation in the town seems as yet in excess of the demand, and the prices first quoted are being reduced. Probably this may be accounted for by the fact that a large proportion of the tickets issued has been purchased by residents in Dundee and the neighbourhood. The General Committee met yesterday, at the Panmure Street Chapel, at 1 p.m.

Professor **Hirst**, one of the General Secretaries, read the report of the Council for the year 1866-7.

Mr. W. **Spottiswoode** then read the report by the treasurer, which was also agreed to.

Mr. **Griffith**, Assistant General Secretary, read the report by the Parliamentary Committee.

REPORT OF THE KEW COMMITTEE.

Mr. J. P. **Gassiot** read the report of the Kew Committee.

The **Assistant General Secretary** then read the report of the committee appointed by the Council of the Association to consider the best means for promoting scientific education in schools. The report, after pointing out that there is already a general recognition of science as an element in liberal education, and stating that general education in schools ought to include some training in science, went on to refer to the difficulties in the way of introducing science into schools, which the committee, however, considered easily surmountable. With a view to the furtherance of the scheme, the committee made the following suggestions:—

1. That in all schools natural science be one of the subjects to be taught, and that in every public school at least one natural science master be appointed for that purpose.
2. That at least three hours a week be devoted to such scientific instruction.
3. That natural science should be placed on an equal footing with mathematics and modern languages in effecting promotions, and in winning honours and prizes.
4. That some knowledge of arithmetic should be required for admission into all public schools.
5. That the universities and colleges be invited to assist in the introduction of scientific education by making natural science a subject of examination, either at matriculation, or at an early period of a university career.
6. That the importance of appointing lecturers in science, and offering entrance scholarships, exhibitions, and fellowships for the encouragement of scientific attainments, be represented to the authorities of the colleges.

In the afternoon the grand floral fête in Baxter Park was opened under very favourable circumstances as to weather; this is considered to be the largest and finest floral and horticultural show ever held north of the Tay. It was again open this morning to private inspection of the members of the Association.

Yesterday evening the first great meeting took place in the Kinnaird Hall, the company being but little assisted on their way to the assembly by the electric light, which was exhibited in front of the High School, under the charge of Mr. Louis Schwendler. At eight o'clock Sir Roderick I. Murchison, F.R.S., acting for Mr. Grove, who was prevented by illness from attending, in a short speech formally vacated the chair to his Grace the Duke of Buccleuch, the president of this year.

The large meeting-hall was crowded in every part, and confusion had been as much as possible avoided by numbering each seat, and not admitting members or associates unless they had previously got their tickets stamped with a similar number. Your correspondent, who was not aware of this judicious regulation till the last moment, would have had a poor chance of hearing the forcible speech of the noble president, were it not that a General Committee ticket carried with it the privilege of admission to the platform.

Sir **Roderick Murchison**, in introducing the Duke of Buccleuch, expressed regret at the unavoidable absence of Mr. Grove, in whose behalf it had fallen to him as a former President, and as one who had filled nearly every office in the Association, to hand over the chair to the President elect.

About a quarter to eight o'clock, considerable excitement was caused by Sir David Brewster having been seen to become suddenly faint. He was conversing with Professor Balfour, who sat behind him, his arm being thrown over the back of the chair, when he ceased speaking, his face became deadly pale, his hand fell from the back of the seat, and he was about to fall, when Professor Balfour sprung forward and caught him. After Sir David Brewster had been extended motionless on the platform, and water brought, in a few minutes he recovered from his swoon, and was carried out of the hall.

After the confusion had subsided, Professor **Phillips** came forward and said: Our highly honoured member, Sir David Brewster, has been affected by the heat of the hall. He is now decidedly better.

The Duke of **Buccleuch**, having taken the chair, said—Gentlemen of the British Association for the Advancement of Science, and ladies and gentlemen,—As to what has fallen from Sir Roderick Murchison, I feel that, whatever bold deeds my ancestors may have done, or may have attempted, perhaps in one sense I have attempted the boldest of them all. If it were only a question of physical endurance, or dashing enterprise, I should not have felt abashed, nor shy, nor disinclined for the encounter. I think the old spirit of the Borderer would have carried me through. I have been told, and perhaps with reason, that it is better and more usual upon such a great occasion as this for the President to prepare his speech or address with care beforehand, to commit it to writing, and give an opportunity of having it put in print for the convenience of the members of the Association, and also of those whose particular vocation and duty it is to communicate to the public that which passes at public meetings. Unfortunately, perhaps, for myself, and still more unfortunately for you, I have not so done. I never in my life attempted to pen an address or to prepare a written speech to be delivered. If I had done so, and had recourse to the productions of the pens and heads of others, I might have read an address to you in flowing language—full of science, full of information; but I could not have pretended that what I read came from myself. I preferred rather to fail by speaking what I had to say direct from myself, as it came from my heart and from my head, than have recourse to the assistance—although most valuable it would have been—of the thoughts and pens of others.

When I consider the nature and intention of this great Association, I cannot but feel that one of the greatest gifts which Providence has bestowed upon man is great intellectual power. It is a talent of the highest price; it is a talent vouchsafed to but few. Happy are those men themselves, and blessed is it for this country and for the world, when they who have the intellectual power have also the will to exercise it, the power to exercise it, and to direct it aright. You will rarely see that any one man possesses the full intellectual power to make himself master of the whole. Ladies and gentlemen, this reminds me that since the last meeting of this Association, and within a very short time, one most distinguished member has been gathered to his fathers—I mean Professor Faraday—one of the most distinguished men in his own branch of science, one who having great intellectual power, and having great personal will, was determined to rise above that position in life in which he happened to be born. Happily for him he took a line, and sought a friend in one who was able to forward his views; and I believe that in his own department of science no man was more prominent than Professor Faraday lived to become. In him we have to mourn one that is lost; but when we mourn one that is lost, is it not an incentive to many others who may have been born in the same position as himself, or may, perhaps, have been born in other positions, in a higher and better position than he, with every opportunity of cultivating science, and instructing themselves in every way? Is it not an incentive to every man who may feel himself possessed of that power to push himself forward quietly, unostentatiously, but at the same time not for the personal pride of position, but for the more generous ambition of being a great benefactor to his country. We heard to-day at the preliminary meeting, a report made upon an important matter—namely, that of having science taught at our public schools—that it should form a portion of the curriculum of study in every school. I quite agree with that, but I think you must not, at all events in the first instance, attempt to push it too far. Give the youth a taste for science, and when they have acquired this taste, those who have an aptitude for the sciences will each be very much inclined to follow a particular science for himself. You can no more drive science down a boy's throat than you can teach mathematics to a horse. (Laughter.) If he has a turn for it, he will take it in; if he has not a turn for it, he will say that it is a greater bore than Latin or Greek; but to teach him the elements of science is of great importance. In every relation of life a knowledge of science is becoming more and more necessary. I need not go further than the town in which we are at present assembled. Where would the prosperity of this town have been had it not been for science. You will say we have manufactures of flax, hemp, jute, and things of that sort; there is not much science in that. Well, go to the cultivation of these plants—go on to the preparation of these plants after they are cultivated, and bring them to this country. Do we not require some amount of science to build those ships, and to navigate them? and when those vessels come to port do we not require some science to produce the docks and harbours in which these vessels lie? Then again, when you come to the manufacture of the raw material, do we not require some science in chemistry and in mechanics; and in mechanics, we require mathematics to begin with? Then, these inevitable faculties are necessary to produce the machinery by which all these raw materials are to be made into useful articles of commerce. Is it not also the case when we come to the cultivation of the soil? What do people do now? It is not the rule of thumb process—the old story, that you must put lime here and farm manure there. You ask, why? The answer is, it stands to reason —because the soil requires that. Standing to reason is a very good answer; but the man who gives it goes by the rule of thumb. We want a man with science and chemistry to tell us why we do these things—why we apply one description of manure to one soil, and one to another; and why, if we apply this description of manure to one place and to another, we apply it to the wrong place. Again, we have many other branches. Take geology for instance. I am sure it would be difficult to say how many hundreds of thousands have been sunk and lost in seeking for that wonderful vein of gold in the shape of coal, and other things which nobody would have dreamt of doing if a question had been asked of any common, ordinary geologist. I was talking a little while ago of scientific education in schools. We want scientific education in our Universities. We want to have natural and physical science taught in our Universities. It is not many months ago since a powerful effort was made to get an endowment for a geological chair in Edinburgh, which, we may say, is the cradle of geology—where it took its rise, and flourishes particularly. Unfortunately that attempt was simply snuffed out. We met with a cold reception. In vain did we say that endeavours had been made to endow the University of Edinburgh, which happens to be very poorly endowed; but the efforts and contributions of almost all those who responded to the application have been directed to founding scholarships and bursaries to enable poor students who thirst for knowledge to avail themselves of the knowledge which might be afforded there; and we thought the public purse might well afford a professor to teach that which was really of national importance. I cannot pretend to go through all the different points and sections which are taken up by this Association. I will only call your attention to one which I take some interest in—namely, meteorology. There, great efforts have been made, and with signal success, by the British Association for the Advancement of Science, more particularly at Kew Observatory. What I and others have urged on the Government of the day is the great importance of having renewed and carried on what were called the storm signals at our different ports. This is of immense value and importance; and I believe much valuable property has been saved, and many valuable lives preserved by the timely hoisting of the drum signifying bad weather. At the Firth of Forth I have seen the drum hoisted indicating tremendous storms of wind, and risks that may be run, and yet not a breath of wind blowing in that particular quarter. Some who had not this simple warning might have said, "We might just as well go out to sea, as there is not a breath of wind here." But then, there comes the newspaper, twenty-four or forty-eight hours afterwards, telling of disastrous gales of winds and shipwrecks upon no very far distant portions of the coast. Well, the great thing I may say with regard to this Association is, that it is not exclusive or repulsive. It will neither expel nor repel others, nor will it seek to include within its sphere other societies that ought more properly to be by themselves. I do not know, gentlemen, that I have any right to trespass any more upon your time—I have trespassed already too long, perhaps. I must, in conclusion, be allowed simply to thank the gentlemen of the British Association for the Advancement of Science for the honour they have done me in placing me in this chair. I know it is no slight honour—I feel it is no slight honour—I also feel it is no slight responsibility—but, so far as in me lies, I will endeavour faithfully to perform my duties, and I hope these duties will not be so performed as to show that you have been entirely deceived in having selected a person for this high position who was totally unfit to be your choice. (Cheers.)

Professor Phillips, in an eloquent and interesting speech, passed in review the progress of the British Association and the work it had done towards the advancement of science during the course of 36 years, and concluded by proposing a vote of thanks to the Chairman for the inaugural address he had just delivered.

Section B.—Chemical Science.

President:—Professor Thomas Anderson, M.D., F.R.S.E. *Vice-Presidents:*—Maxwell Simpson, M.D., F.R.S.; Professor Williamson, F.R.S.; J. Lothian Bell, F.C.S.; W. Odling, M.B., F.R.S., Dr. Gilbert; Professor J. S. Brazier; Dr. Penny. *Secretaries:*—Professor Liveing, M.A., F.C.S.; Dr. Russell, F.C.S.; Dr. Crum Brown, F.R.S. *Committee:*—J. Attfield, Ph.D., F.C.S.; Dr. Barford, F.C.S.; A. R. Catton, F.C.S.; R. Calvert Clapham, F.C.S.; W. Crookes, F.R.S; John Davy, M.D., F.R.S.; Dr. Heddle; W. E. Heathfield, F.C.S.; P. Spence, F.C.S.; J. Spiller, F.C.S.; E. C. C. Stanford, F.C.S.; Dr. R. Angus Smith, F.R.S.

In the High School.

President's address.

A. R. Catton.—Report on the Synthesis of certain Organic Acid.

A. R. Catton.—On the Synthesis of Formic Acid.

A very animated discussion took place upon these synthetical papers between Professor Wanklyn and Mr. Catton, in which each speaker defended his own views, and attacked those of the other in very energetic language.

J. A. Wanklyn and R. Schenk.—On the Synthesis of Caproic Acid.

J. A. Wanklyn.—Action of Sodium on Valerianic and similar Ethers.

P. T. Main and A. R. Catton.—On a new Synthesis of Ammonia.

J Spiller.—On the Decay of Stone.

W Weldon.—On the Regeneration of the Oxide of Manganese.

To-day the sections commenced their regular work. The committee of Section B met at half-past ten a.m., and at eleven the President, Dr. Thomas Anderson, F.R.S.E., opened the proceedings with the following address:—

On many previous occasions the British Association has met in places which have afforded the chemist most valuable opportunities of seeing the principles of his science reduced to practice, and the various papers which have been read in this Section on these subjects, and the discussions which have arisen regarding them, have formed a very interesting department of its proceedings. At the present meeting little of this is likely to engage our attention, for though the manufactures of Dundee have probably increased during the last ten or fifteen years, in a more rapid ratio than those of any other town in the kingdom, they have taken a direction which gives but little scope for the applications of chemistry, so that with the exception of a few of the simpler operations of the dyer, there is really scarcely anything which need specially attract our attention. Under these circumstances it may be fairly anticipated that the business of the Section will be more particularly occupied with the discussion of the great principles of the science which to the general public are often less interesting, and regarded as the exclusive province of those engaged in scientific study, and not sufficiently recognised as being the only sure foundation on which the superstructure of practical progress can be raised.

The consideration of these general principles is, however, at the present moment a matter of the very highest importance, for the science of chemistry is in a state of transition. The immense accumulation of facts which has been made during the last twenty or thirty years, has not only increased her bounds, but has shown the insufficiency of those principles on which the chemist was formerly ready to rely with almost implicit confidence, and introduced changes amounting to a revolution which have had the effect of unsettling the views formerly entertained by almost all chemists, without as yet introducing anything conclusive in their place. The atomic theory, which at the commencement of the present century explained with clearness and precision all the facts of the science then known, has proved itself (at least in the form in which Dalton left it) no longer sufficient for the purpose. At that time the knowledge of chemists was confined to a comparatively small number of compounds, among which those of oxygen had so preponderating an importance that the science of the time might almost be described as the chemistry of oxygen. At the present moment, if we were to attach to it the name of any individual element we should most unquestionably describe it as the chemistry of carbon, for it is in the study of its compounds that all the difficulties with which the chemist has now to contend have had their origin. At a comparatively early period indeed, doubts were expressed as to the sufficiency of the atomic theory of Dalton, and Ampère especially suggested that the chemical atom might with advantage be considered to be a congeries of smaller particles; but this and other analogous additions to the original conception of the chemical atom, having no immediate bearing on the facts then, or even now known, have never been accepted by chemists, or received from them more than a very passing notice, and were not unfairly considered to be unnecessary complications of the theory. It was left for time to accumulate facts, for which Dalton's theory supplied no explanation of any kind, and these were at first neglected, but as their number increased, their explanation was evaded by the invention of names intended to group together facts supposed to be dependent on similar causes. Such names as catalysis, allotropy, and the like really explained nothing, they are little better than scientific lumber-rooms, in which unexplained facts are stowed away until it suits our knowledge or our convenience to classify and explain them. I am far from asserting that this mode of grouping facts supposed to have something in common, has not its advantages, provided only it be distinctly understood that it is the grouping of ignorance. The risk lies in the name being accepted as an explanation, and inquiry being thereby retarded, and something of this sort has indeed occurred, for though these facts were admitted to be beyond the scope of the atomic theory, they were quietly set aside; things went on as they were before, and it was not till the introduction of the theory of atomicity, which shows itself in every chemical fact, that the doubts which had been long gathering in the minds of all thoughtful chemists found distinct expression. I do not on the present occasion propose to discuss in detail the effect which the introduction of this view has had upon chemical theory, further than to remark that it renders it necessary either to abandon altogether the atomic theory of Dalton, or to introduce into it such modifications as fundamentally alter its entire character, and make it substantially a new theory. The former is an alternative which some chemists will be greatly disinclined to adopt. They will not willingly abandon a theory which has admittedly done admirable service, which at its first introduction established order and regularity, where confusion and disorder previously reigned supreme, and under whose influence the science has attained its present goodly proportions. Others again may be of opinion that the atomic theory has done its work and in the future is less likely to act as an assistance than as a hindrance to progress, by forcing us to consider all facts in its particular light, and causing us to overlook relations which might be at once detected by an unbiassed mind.

This latter opinion has been very strongly expressed by Sir Benjamin Brodie, and in the calculus of chemical operations, which he has recently made public, we have the first systematic attempt which has been made to express the constitution of chemical compounds, by a method in which the idea of an atom has no place. As this is the most important chemical doctrine which has been put forward for many years, and must if accepted materially alter our present views, I shall venture to consider it in some detail, premising, however, that as only the first part of the investigation has yet been made public, any opinion I may now express regarding it, may be liable to modification when the entire investigation is published.

Sir B. Brodie, as has been already observed, discards altogether the idea of an atom, and compares with one another the weights of different substances in the gaseous state which are capable at the standard temperature and pressure of filling a unit of space, which is the bulk of 1,000 cubic centimetres. If we consider this space to be empty, and fill it with hydrogen, a chemical operation is performed which is represented by the symbol a, expressing the fact, that the weight so introduced is chemically indivisible. If now in place of hydrogen, oxygen be introduced, the unit of space is filled by a quantity sixteen times as great, but this weight is not indivisible, as is at once apparent if we notice what happens when oxygen is introduced into the unit of space already filled with hydrogen. In that case a second operation is performed on it, in which a weight eight times as great as that of the hydrogen is introduced, and water is the result. The quantity of oxygen which fills the unit of space must therefore be regarded as divisible, and this is expressed by assigning to it the symbol $\vartheta 2$, indicating the fact that two identical operations are required to fill the unit of space with oxygen. By the same line of argument it is concluded that sulphur, selenium, etc, must be similarly constituted, and they are accordingly represented respectively by $\theta 2\lambda 2$, etc. So far it will be observed that the system is merely a modification of that at present used by chemists for expressing the laws of gaseous combination, excepting that all substances, compounds as well as elements, are referred to the unit of space, while, according to our present plan, the former are referred to two units of space, and the latter to one. But when the compounds of chlorine and the allied elements, with hydrogen, are to be represented according to Sir B. Brodie's system, it at once becomes apparent that some further hypothesis must be introduced if they are to be referred to the same volume. When the quantity of hydrogen represented by the symbol a, unites with chlorine, the product fills two units of space, and as, according to the fundamental hypothesis, a is indivisible, the question is to obtain some means of expressing without fractions the quantity of hydrochloric acid which fills the unit of space. This end Sir Benjamin attains by assuming that chlorine is itself a compound of hydrogen with an unknown element to which the symbol χ is assigned; chlorine being $a\chi 2$, and formed by these operations, one being hydrogen, and the other two which are identical, result in the introduction into the unit of space of two quantities of a hypothetical substance χ, whose weight is 17·25, and according to this view, when hydrogen and chlorine unite, the action is expressed by the equation:

$$a\chi 2+a=2a\chi$$

On precisely the same principle iodine, bromine, nitrogen, phosphorus, antimony, and bismuth, must also be hydrogen compounds. It is obvious, therefore, that Sir Benjamin's system involves a very large amount of hypothesis, for it assumes that a considerable number of those substances hitherto regarded as elements are really compounds. I do not imagine that much difficulty will be experienced by any one in admitting the possibility of this, for I apprehend there is no chemist who imagines those bodies which we call elements to be the ultimate constituents of matter, or who doubts that the time, though still far distant, will come when they may be resolved into simpler substances. But when we come to reduce these speculations to a definite form, and seek to make them part of the science itself, it becomes essential to subject them to a very close and searching scrutiny.

In order to justify their assumption, it seems to me necessary either that they should be supported by experimental evidence, or that they should afford the means of tracing out unsuspected relations, and thus extending the bounds of the science, or, at all events, that they should involve the minimum amount of hypothesis. Now, as regards the first of these, it is unnecessary to observe that there is not one tittle of evidence to show that chlorine is a compound any more than hydrogen itself. As far as extending the bounds of the science is concerned, we must look for an answer to the future, and it may be expected that in the remaining parts of the investigation, which it is to be hoped will soon be made public, it will be shown how the method may be used for this purpose; but, in the meantime, I confess I am unable to see how it can be used so as to open up new fields of inquiry, and it is certain that it leaves unexplained all those anomalies which are encountered in the existing system. Neither can it be asserted that the system involves the minimum amount of hypothesis, for, in point of fact, the assumption of the compound nature of certain of the elements is rendered necessary by the fundamental hypothesis that a is indivisible. If it be assumed to be divisible, the necessity for holding those elements to be compound at once falls to the ground, and I confess it appears to me that we should require very clear evidence of the advantages it offers before we accept a hypothesis involving so many others. The question must at best be considered as still *sub judice*, and the method is not likely to meet with general acceptance until it is supported by a much larger body of facts than those we at present have.

While Sir B. Brodie's theory is one from which the idea of atoms is excluded, it is important to notice that it is by no means incompatible with them, and it even appears to me that though it may suit our convenience to consider matter in relation to space only, the real subject of inquiry is not the unit of space, but the unit of matter, and to it we must eventually come. If I hold, as I most undoubtedly do, that the atomic theory of Dalton must sooner or later be abandoned, it is not because I do not believe in the existence of a unit of matter. Whether we assume it to be a hard spherical particle, a centre of force, or a vortex produced in a perfect ether, is another question; but it seems evident that some kind of molecular hypothesis is indispensable for the explanation of physical phenomena, and it is scarcely possible to doubt that some connection must exist between the chemical and the physical unit of matter. In the mean time it is only by the most cumbrous and improbable assumptions that the existing atomic theory can be made to fit in with the facts which chemistry has recently discovered, and of these the theory of atomicity is one which can scarcely be connected with it at all. The fact is that theory is a merely temporary hypothesis, constructed to keep before our eyes the tendency which substances have to form compounds of certain definite forms, under special circumstances; and it is scarcely possible to doubt, that in 20 or 30 years it will have passed away and have been replaced by something of a more satisfactory character. Meanwhile its important influence on the recent progress of chemistry is too obvious to be disputed. It is only to be regretted that so many conflicting modes of considering the atomicities of the elements should have been introduced by different writers. Into the consideration of this matter I should have been glad to have entered at some length, but I feel that I have already detained you too long from the actual business of the Section, and no doubt opportunities will arise in the course of the business for individuals expressing their opinions on this and other subjects. Among these the mode of expressing the symbols of chemical compounds, which was objected to long since by Sir John Herschel, and has been again brought into prominence by the publication of Sir B. Brodie's paper merits attention. The present unsettled state of chemical nomenclature, so inconvenient to the teacher, ought also to be discussed, and it might even be well to consider whether a committee should not be appointed to ascertain how far it might be possible to adopt a uniform system. Nor do I think we ought to separate without recording our opinion on the subject of better and more extended scientific education. The events of the Paris Exhibition have brought our deficiencies in this respect very conspicuously before us, and show us how much we have yet to do. That we have made progress in this respect is not to be doubted. Science is much more cultivated than formerly,—it is becoming more and more a branch of general education. Much, however, still remains to be done in this direction, especially in Scotland, and it will no doubt surprise many of my audience to hear that chemistry and natural history are still excluded from the course of study for degrees in arts in the Scotch universities. Of late years the study of this and other departments of natural science has been introduced to some extent in schools both in England and Scotland; but, I must confess, with but little advantage, so far as my experience goes. The failure, I think, lies in the kind of instruction offered; the usual practice having been to give a course of lectures from which the discussion of principles and of everything which exercises and developes the mind, is eliminated, and only that which it is supposed will entertain or surprise is retained, and boys are thus led to look upon science merely as a pastime. They are shown enough to see the difference between this and the closer and more severe system of study pursued in the other departments of their education, and they are apt either to avoid work altogether, or to acquire their knowledge in a superficial manner. The whole system of teaching science to school-boys is a subject which merits far more attention than it has yet received, and the success of the movement must greatly depend on the method of teaching adopted. All these, however, are subjects the discussion of which would carry me far beyond the limits of those introductory observations with which it has been customary to open the business of the section. It must be left for its members to bring forward their own views on these and kindred questions.

Professor WILLIAMSON:—I rise to propose the thanks of this meeting to our worthy President for the address with which he has just favoured us. He has touched on several of the most weighty and important matters which are interesting to us as theoretical chemists, and he has very justly remarked upon the very rapid progress which our science has been undergoing of late years, especially in the way in which existing theories have been made or modified. And it is surely a most encouraging proof of the life which is in our science to see, besides the discovery of facts, these immense evidences which have manifested themselves in all directions. Our distinguished President has also touched on a peculiarly interesting topic to all persons, namely, the introduction into general education of those important results which chemists and others have attained in their special departments. It is certainly to be regretted that these results should remain as yet rather unknown in our schools. It is one illustration of the slowness with which we excuse many results of great benefit to see that these great discoveries are not yet introduced into general education; and certainly we owe our President thanks for the formal way in which he has drawn attention to the importance of introducing scientific education into schools.

The practical subjects which we heard treated of with so much interest in his able address are so fruitful and weighty that I am sure the section will concur with our president in a wish that it may form the subject of one of our meetings, and I would venture to suggest that some early day should be fixed for—I was going to say a field day on the subject of chemical theories.

It seems to me that it is one of our strong characteristics that we are quite as much inclined to the practical as well as to theoretical views, and though we are perhaps to have one field day on theories, I hope there will be many such on the more practical questions.

With regard to the practical introduction of science I ought not to omit to mention that we have present to-day a distinguished member who has collected on the Continent a great amount of facts as to the progress of scientific and technical arts, more especially metallurgy and engineering. I allude to Mr. Lothian Bell, and I hope he will favour us with some of the results of his observations on the subject.

I beg to move a vote of thanks to Professor Anderson, and I am sure the section will be glad to see the printed address of our distinguished President.

The following papers were then read:—

"*On the Decay of Stone; its Cause and Prevention*," by J. SPILLER.

For several years past I have been occupied at intervals in studying the causes of the decay of stone, and in experimenting with such chemical reagents as appeared to offer any promise of being usefully applied as means of prevention. At an early state of the investigation I arrived at the conclusion that the corrosive action of sulphurous and sulphuric acids in the atmosphere, resulting from the combustion of coal fuel, operate, in large towns especially, in a very destructive manner upon dolomite and the numerous class of limestones commonly employed in our public buildings. This chemical action, aided no doubt by the simultaneous attack of carbonic acid and moisture, and in the winter season further supplemented by the disintegrating effects of frost, must, I conceive, furnish a sufficient explanation of all the facts observed.

I would here remark that Dr. Angus Smith, Mr. Spence, and others have already directed attention to the immense scale of production of these sulphur acids, and have even quoted statistical data showing the extent or degree of pollution of the air from this cause in the manufacturing districts of Lancashire. When it is known that the *best* class of coal (and coke) contains usually one per cent of sulphur, and that this proportion, reaches a treble equivalent when stated in the form of the final oxidised product,—hydrated sulphuric acid,—it follows that a ton of coal of this high quality necessarily evolves during its combustion nearly 70lbs. of oil of vitriol. Here, then, is the origin of the sulplates which we find invariably present in the loosened crust of decayed stones, whether of calcareous or magnesian character. I have tested numerous samples of dolomite, Caen, Bath, and Portland stones fresh from the quarry, and in no instance found more than a trace of ready formed sulphate, whereas scrapings taken from the decayed portions of the stone of the New Palace at Westminster are bitter to the taste in consequence of the comparatively large amount of sulphate of magnesia formed during a few years' exposure to the sulphurous gases occurring in a metropolitan atmosphere. Caen stone from several buildings and localities, Portland stone, and even old faces of chalk cliff in the neighbourhood of Woolwich, were in like manner found to contain appreciable quantities of the sulphate of lime having undoubtedly a similar origin.*

A close examination into the circumstances attending the decay of stone at the Houses of Parliament invariably shows an increased liability to corrosion under the projecting eaves and mouldings, and at such sheltered parts of the stone surfaces as are usually covered with soot and dust, and are in a position to retain for the longest period the moisture absorbed during a season of rain. The plain ashlars are throughout very much less affected than the buttresses, gablets, and other elaborately carved and highly ornamental portions of the work, which appear to be more assailable by reason of their relatively greater superficies. In many places the disintegrated stone exhibits white crystals of the sulphate of magnesia, which, alternately dissolving and recrystallising in the pores of the stone, may be conceived to exert a disruptive action sufficient to account for the scaling and fracture of the dolomite which has been so often made the subject of complaint and regret.

With the view of overcoming some of these difficulties I

---

* Caen stone, Northfleet College.
Decayed exterior portion contained of sulphate of lime 3·4 per cent.
Interior of same stone (sound) " " nil.
Caen stone. St. John's Church, Woolwich.
Scales of decayed stone contained of sulphate of lime 4·6 per cent.
Interior portions (sound) " " nil.

submitted a plan to the Royal Commissioners charged with inquiring into the decay of stone at Westminster, in May, 1861, which consisted in the application to the cleaned surfaces of the stone of an aqueous solution of superphosphate of lime,—a salt remarkable for its action in hardening the surfaces of chalk, Caen stone, or other calcareous building stone to which it may be applied either by brushing or immersion, and which acts upon the carbonate of lime in the stone, giving rise to the formation of Bodeker's salt (crystallized diphosphate of lime $=2CaO,HO,PO_5+4Aq.$). My suggestion received a practical trial in a competition to which other five candidates were admitted by the Right Hon. the First Commissioner of her Majesty's Works, in April, 1864, and in regard to the work executed on that occasion upon three faces of the Westminster Palace I fearlessly await the Government report. In the meanwhile, another promising scheme for the treatment of the decayed stone, especially applicable to dolomite, has been submitted by me to the notice of the First Commissioner, but this new proposal has not yet been selected for trial. It consists in the employment of baryta conjointly with the hardening salt, so that a base may be presented which is endowed with the power of destroying the soluble sulphate of magnesia in the pores of the stone, forming with it the remarkably insoluble sulphate of baryta, and, at the same time, engaging the magnesia in one of its most difficulty soluble combinations. On a recent occasion I have applied this process on a small scale to some Caen stone facings at St. John's Church, Woolwich, which were badly decayed.

With reference to the application of the superphosphate to decayed Caen stone I am able to refer to several successful examples of its use. In the year 1862 I applied the process upon some alms-houses forming part of Northfleet College, where the decay has been completely stopped. In 1864 I operated upon a window and buttress of St. John's Church, Woolwich; and in the following year the façade of the Grand Hotel, Brighton, was treated by my process. With respect to Portland stone, the earliest experiments were made at the Army Clothing Establishment, Woolwich, where in 1861 some decayed window-sills were treated, and with perfect success. I have some interesting results to record in connection with the treatment of Portland stone, which serve to illustrate the increased hardness and strength, and the diminished rate and capacity of water absorption attending the employment of the superphosphate. Small cubes of Portland stone, each of 1·3 inch dimensions, were treated with the phosphate solution and left to dry in the air; these were then subjected to gradually increasing pressure, until crushed, between plates of lead in the American testing machine, at the Royal Gun Factory; and the breaking weights of two precisely similar cubes of the native stone were at the same time carefully determined. The results were as follows:—

		Crushing weight.	
I.	Stone in original condition	3,650	lbs.
II.	" " "	3,800	"
	Mean	3,725	"
III.	Stone treated with superphosphate	5,375	lbs.
IV.	" " "	5,500	"
	Mean	5,437	"

Thus acquiring an increased strength, amounting almost to 50 per cent. The relative hardness of the stone before and after treatment could be readily ascertained by mutual friction of their surfaces, and also by scratching with a pointed instrument of copper, which metal proved to possess a degree of hardness intermediate between the original and treated Portland stones.

The porosity of the stone as indicated by the amount of water absorbed in equal intervals of time proved to be greatly diminished in the case of the treated cubes. On this point several experiments were made, the stone being first weighed in the air-dried condition, and then immersed in distilled water at the temperature of 60° Fahrenheit for the several periods named, and the increase of weight in each case noted.

"*Whit Bed*" *Portland.*

	Original stone. Grs.	Treated stone. Grs.
Weight of cube (dry)	1421	1420
Water absorbed in 5 min.	70	7
" " 15 min.	91	8
" " 30 min.	91	12
" 1 hr. 30 min.	92	25

"*Base Bed*" *Portland.*

	Grs.	Grs.
Weight of cube (dry)	1291	1335
Water absorbed in 5 min.	120	20
" " 15 min.	122	33
" " 30 min.	124	50
" 1 hr. 30 min.	126	78

These results have been further controlled by other experiments in which the *same block* was used in the original condition, and again after treatment with the superphosphate. It will be noticed that the advantage of the process is most clearly apparent in the case of the denser and more compact variety of Portland known as the "Whit Bed" which alone is employed for external building purposes; the other—the "Base Bed"—is softer and only fit for internal decoration, and its texture is so porous that in becoming saturated it absorbs nearly 10 per cent. of water.

Samples of Mansfield dolomite absorbed amounts of water varying in different specimens from 6 to 8 per cent. After treatment by my process the degree of absorption was reduced one-half; and the results were even more favourable in the case of Caen stone.

The cost of materials employed in the treatment of stone according to this plan is very trifling, and bears but a small proportion to the cost of labour necessarily expended upon the cleaning and preliminary preparation of the stone before the solution can be applied. One gallon of solution will cover about 300 feet superficial, when two coatings are applied upon Caen or Portland stone. The superphosphate employed must not contain any appreciable amount of sulphuric acid, and the specific gravity of the solution, when diluted for use, should be about 1,100.

The facts now stated have, it is believed, but a minor interest for the inhabitants of these parts of the United Kingdom; for with Aberdeen granite and Craigleith sandstone at command there will be no need to resort to chemical methods of preservation.

The PRESIDENT said: I am sure the section will agree in expressing their best thanks to Mr. Spiller for his very interesting communications on a subject of so very great importance; which all of us appreciate, whether we be chemists or not. The destruction of so very magnificent buildings as the Houses of Parliament has been naturally looked upon as a most serious question, and we have looked forward with the greatest possible interest to the result of these experiments, so as to prevent further decay. Mr. Spiller's account of the result of his process is, therefore, peculiarly interesting to us, and the observations he made are of peculiar value, inasmuch as they afford us some explanation of the cause of this decay. We can see what is peculiar in the decay, and it shows us how important it is for us to bear this in mind when we are making arrangements such as those in connection with the House of Parliament. At the time when the erection of the building was commenced immense care was bestowed in the selection of stone, and the peculiar magnesian lime-stone was selected because it was found that all the buildings erected with it in the middle ages were in an entire state of preservation. The president concluded by saying that it had now been discovered that the atmosphere and other influences of the city had affected the stone; but Mr. Spiller's communication would be valuable, as his discoveries were of great importance in connection with the processes for the prevention of decay.

After the President's remarks on Mr. Spiller's paper, a very important discussion took place, in which Professor Ansted, Mr. Spence, Mr. Ansell, and others, took part.

The next paper—not in order of reading, but in practical importance,—was

"*On the Regeneration of Oxide of Manganese in Chlorine Stills*," by Walter Weldon.

The author stated that the essential features of the process consisted, firstly, in the use of an *artificial* oxide of manganese, capable of liberating from a given quantity of hydrochloric acid about twice as much chlorine as could practically be obtained therefrom by means of a 70 per cent. native oxide; and, secondly, in a simple method of reproducing the artificial oxide from the "still-liquor." This recovery of the artificial oxide might be performed in the stills themselves, so that a charge of manganese, once placed in a still, might always remain therein, continually generating chlorine; and not only never requiring removal, but never undergoing diminution of properties, nor suffering loss by waste.

The "still-liquor" produced in this process contained no free acid, but was a neutral solution of protochloride of manganese, mixed only with a little chloride of calcium. The artificial oxide was recovered from this still-liquor by adding thereto an equivalent of lime, and then injecting atmospheric air. Double decomposition took place between the lime and the chloride of manganese, producing chloride of calcium, which entered into solution, and insoluble protoxide of manganese, which the oxygen of the injected air rapidly peroxidised. When the artificial peroxide thus produced had been allowed to subside, and the greater portion of the solution of chloride of calcium in which it was formed run off from it, it was ready to be treated with hydrochloric acid, from which it then liberated chlorine, with reproduction of exactly such a "still-liquor" as was commenced with. From this point the series of operations described was to be repeated as before, —and so on continually.

The oxide of manganese so obtained was *hydrated* in an exceedingly fine state of division, and it shared with all such artificial hydrates the property of being far more readily soluble in acids than a hard, compact, anhydrous *native* oxide. In fact, instead of requiring, like the native oxide, long digestion, aided by heat, in a large excess of acid, the artificial oxide dissolved, even in the cold, and with extreme rapidity, in an equivalent of acid, producing a neutral "still-liquor." Hence, the full theoretical yield of chlorine could be practically obtained from simple equivalents of acid and oxide, and this with a considerably less expenditure of time, labour, and fuel than the inferior yield obtained by means of the native oxide required. When using a 70 per cent. native oxide it was rarely found possible to obtain in the free state more than *one-sixth* of the chlorine contained in the hydrochloric acid put into the stills; but an artificial oxide of only 55 per cent. liberated *one-third* of the chlorine contained in the acid put into the stills, and in less time, and at a less cost for labour and fuel, than the native oxide required for the liberation of half the quantity. A 55 per cent. oxide thus enabled a given quantity of hydrochloric acid to yield twice as much bleaching powder as a 70 per cent. native oxide did, saving in this item alone from £5 to £7 per ton of bleaching powder.

This evening Professor Tyndall, F.R.S., will deliver an experimental lecture in the Kinnaird Hall, "*On Matter and Force*." This, although addressed to working men, promises to be the most attractive lecture of the meeting. At the same time there will be an artistic and industrial exhibition and soiree in the Volunteer Hall. I have just returned from a private view of this, and consider that it will compare favourably with similar exhibitions at former meetings of the Association. The walls of the large Hall are covered with paintings, ancient and modern, of the most valuable description. Amongst the paintings was an excellent likeness of the late Professor Faraday, but it was perched in such an elevated position that few would notice it. This might surely have taken the place of some of the local worthies on the line.

There are also several excellent photographs exhibited, including specimens of Mr. Woodbury's new micro-photosculpture process, or mode of representing in relief microscopic objects; (these will be described in the chemical section;) a very fine example of the Woodbury-type, from a negative by W. Bingham. Mr. Spiller exhibits a selection of military photographs; Mr. H. Butler shows some beautiful photolithographic reductions; and Mr. H. B. Pritchard photographs upon silk, satin, cambric, etc. There are also exhibited a large collection of fossils, shells, fishes and reptiles preserved in spirit, and other objects of interest.

Dundee, Sept. 12, 1867.

The meeting of the British Association, which has just terminated, must be regarded as most successful either from a scientific, financial, or social point of view. The actual number of members and associates at this meeting is 2,444 (this nearly equals the Aberdeen meeting (2,580) in the year 1859, when the Prince Consort was President): and the happy combination of science and relaxation which each day's programme has provided will cause the past week to be remembered with pleasure.

The attendance in the Sections was better than could have been anticipated, and the earnestness of the frequenters of Section B was shown, if not by the large attendance, at all events by the number of papers set down each morning to be read, and by the length and interest of the discussions which the more important of these papers elicited.

Every year the advantage of these autumnal meetings becomes more and more apparent. The value does not, however, arise from a diligent attendance at the Sections, but from those impalpable influences which result from a lounge in the reception-room—a picnic or excursion to some place of note in the neighbourhood—a look in at the B.'s, the Red Lions, or the Eastern Club. Men, who before only knew each other in the pages of a scientific journal, here meet in friendly companionship, and the keen scientific antagonist becomes a personal friend for life. A controversy which has been dragging on for years is settled by ten minutes' personal explanation; and opponents who are rapidly approaching the orthodox scientific intensity of hatred, carry away from such a meeting mutual forbearance and respect. These are precious results, and if the sections are of no other use, they have the inestimable advantage of drawing men of kindred pursuits together from all parts of the kingdom, and giving them an excuse for a week's holiday under the convenient pretence of attending a scientific meeting.

The liberality extended to visitors by residents in the neighbourhood has been unbounded, every mansion having been full of guests. Lord Kinnaird has shown especial hospitality to the frequenters of Section B, and amongst the chemists staying at his seat—Rossie Priory—have been Dr. Angus Smith, Mr. Crookes, Mr. Spiller, and Mr. Ansell, the inventor of the fire-damp indicator.

Last week I mentioned that the reports of the Council and of the Parliamentary Committee had been presented to the Association. These contain some remarks which cannot fail to interest those readers of the Chemical News who are advocating the introduction of scientific education into schools. At the last meeting of the Association, the committee of recommendations referred to the Council certain resolutions which had been adopted by the committees of two sections relative to the teaching of natural science in schools. The Council, fully impressed with the importance of the subject, appointed a special committee for the purpose of inquiring into the question, and of preparing a report thereon. This committee consisted of the general officers of the association, the trustees, the Rev. F. W. Farrar, M.A., F.R.S., the Rev. T. N. Hutchinson, M.A., Professor Huxley, F.R.S., Mr. Payne, Professor Tyndall, F.R.S., and Mr. J. M. Wilson, M.A. 'The Council having considered the report presented by this committee, adopted the recommendations contained therein, and resolved that the report be submitted to the general committee at Dundee. These recommendations were given in our last number.

The Parliamentary Committee state that the attention of the public appears to have been awakened to the necessity for introducing scientific teaching into our schools, if we are not willing to sink into a condition of inferiority as regards both intellectual culture and skill in art, when compared with foreign nations. The voluntary efforts of the masters of two of our great schools to add instruction in natural science to the ordinary classical course are deserving of all praise; and some evidence of their success may be derived from the interesting fact—disclosed in the able report of the committee appointed by the Council of the Association to consider this subject—that some of the boys at Harrow have formed themselves into a voluntary association for the pursuit of science.

This has formed the subject of a special discussion in the Committee of Section B, who have recommended "that a committee be appointed to inquire into the present methods of teaching chemistry and physics in schools of various classes, and to suggest the best means of furthering it in accordance with the recommendations of the report."

I mentioned last week that a lecture was to be delivered on Thursday evening,

"*On Matter and Force.*" By Professor Tyndall, F.R.S.

This lecture was not addressed to members of the British Association, but to working men, of whom nearly 3,000 were present, the large Kinnaird Hall being crowded to suffocation. To give the lecture at length would occupy more pages than can be well spared. I cannot refrain, however, from quoting some extracts from one of the most eloquent addresses which this gifted orator has ever delivered. The subject matter of the lecture offered no special interest to those who are in the habit of listening to this philosopher in his home—the Royal Institution, but not a word of experiment was lost upon the auditors, who testified their admiration of the noble and high-toned sentiments by silent rapt attention, and of the brilliant experiments by enthusiastic applause, occasionally so prolonged that the lecturer was obliged to beg them to moderate their cheering, or he should be obliged to extend the hour and a half allotted to him to two hours. Professor Tyndall's language is always elevated in tone, and his speculations bold and fearless; and those who listened to the climax of tumultuous applause which followed his splendid peroration, looked in vain for any evidence of that intolerance of free-thought which is supposed to be a national characteristic north of the Tweed.

Professor Tyndall commenced by remarking on the avidity with which the working men of London seized the opportunities afforded them by the evening lectures delivered every year by the Professors in the Royal School of Mines. It was a noteworthy fact that these lectures were but rarely of a character which could help the artisan in his daily pursuits. It was a pure desire for knowledge, as a thing good in itself, and without regard to its practical application which animated these men.

"They wish to know," he continued, "more of the wonderful universe around them; their minds hunger for this knowledge as naturally as their bodies hunger for food, and they come to us to satisfy this intellectual want. It is easily argued as a plea for science that it affords great material benefits. So it does. No doubt of it. Without science your Dundee would be a very small place indeed. But still the scientific discoverers—those high priests, so to say, of Science—they are, I assure you, in this work very rarely actuated by a desire for practical application at all. Take that great man whose name I can hardly trust my lips to utter—that man whom I loved—and who has lately gone from this earth—that man Faraday. That man—a poor book-binder's apprentice—has done more for practical science than dozens of your practical men added together; and he has done it without ever caring to gain a shilling by it. He did it because he loved science; and I say it behoves the Legislature to know that the real workers in science are not those who are always trying to turn it to a practical account. They love science for itself, and their desire is to understand and know all the phenomena of this glorious universe.

Whether it be a consequence of long-continued development, or whether it be an endowment conferred once for all on man at his creation, we find him here gifted with a mind, curious to know the cause of things, and surrounded by things which excite its questionings, and raise the desire for an explanation. It is related of a young Prince of one of the Pacific Islands, that when he first saw himself in a looking-glass, he ran round the glass to see who was standing at the back He wished to know the cause of what he saw. And thus it is with the general human intellect when it regards and ponders the phenomena of the external world. It wishes to know the causes and connections of these phenomena. What is the sun, what is the earth, what should we see if we came to the edge of the earth and looked over? What is the meaning of thunder and lightning, of hail, rain, storm, and snow? Such questions early presented themselves to men, and by and by it was discovered that this desire for knowledge was not implanted in vain. After many trials it became evident that man possessed the power of solving such questions—that within certain limits the secret of the universe was open to the human understanding. It was found that the mind of man had the power of penetrating far beyond the boundaries of his five senses; that the things which are seen in the material world depend for their action upon things unseen; in short, that besides the phenomena which address the senses, there are laws and principles and processes which do not address the senses, but which must be, and can be, spiritually discerned.

Now, there are two thing which form, so to say, the substance of all scientific thought. The entire play of the scientific intellect is confined to the combination and resolution of the ideas of matter and force. Newton, it is said, saw an apple fall. To the common mind this presented no difficulty and excited no question. Not so with Newton. He observed the fact; but one side of his great intellectual nature was left unsatisfied by the mere act of observation. He sought after the principle which ruled the fact. Whether this anecdote be true or not, it illustrates the fact that the ordinary operations of nature, which most people take for granted as perfectly plain and simple, are often those which most puzzle the scientific man. To the conception of the matter of the apple Newton added that of the force that moved it. The falling of the apple was due to an attraction exerted mutually between the apple and the earth. He applied the idea of this force to suns and planets and moons, and showed that all their motions were necessary consequences of the action of this force of attraction. He proved that the planetary motions were what observation made them to be, because every particle of matter in the solar system attracts every other particle by a force which varies as the inverse square of the distance between the particles. He showed that the moon fell towards the earth, and that the planets fell towards the sun, through the operation of the same force that pulls an apple from its tree. And this all-pervading force, the conception of which was necessary to Newton's intellectual peace, is called the force of gravitation. All force may be ultimately reduced to a push or a pull in a straight line; but its manifestations are various, and sometimes so complex as entirely to disguise its elementary constituents.

Long thinking and experimenting on the materials which compose our world have led philosophers to conclude that matter is composed of atoms from which, whether separate or in combination, the whole material world is built up. The air we breathe, for example, is mainly a mixture of the atoms of two distinct substances, called oxygen and nitrogen. The water we drink is also composed of two distinct substances, called oxygen and hydrogen. But it differs from the air in this particular, that in water the oxygen and hydrogen are not *mechanically* mixed, but *chemically* combined. In fact, the atoms of oxygen and those of hydrogen exert enormous attractions on each other, so that when brought into sufficient proximity they rush together with an almost incredible force to form a chemical compound.

One consequence of the clashing together of the atoms is the development of a great amount of heat. What is this heat? How are we to figure it before our minds? I do not despair of being able to give you a tolerably distinct answer to this question. Here are two ivory balls suspended from the same point of support by two short strings. I draw them thus apart and then liberate them. They clash together, but, by virtue of their elasticity, they quickly recoil from each other, and a sharp vibratory rattle succeeds their collision. This experiment will enable you to figure to your mind a pair of clashing atoms. We have, in the first place, a motion of the one atom towards the other—a motion of translation, as it is usually called. But when the atoms come sufficiently near each other, elastic repulsion sets in, the motion of translation is stopped and converted into a motion of vibration. To this vibratory motion we give the name of heat. Thus, three things are to be kept before the mind—first, the atoms themselves; secondly, the force with which they attract each other; and thirdly, the motion consequent on the exercise of that force. This motion must be figured first as a motion of translation, and then as a motion of vibration; and it is not until the motion reaches the vibratory stage that we give it the name of heat. It is this motion imparted to the nerves that produces the sensation of heat.

It would be useless to attempt a more detailed description of this molecular motion. After the atoms have been thrown into this state of agitation, very complicated motions must ensue from their incessant collision. There must be a wild whirling about of the molecules. For some time after the act of combination, this motion is so violent as to prevent the molecules from coming together. The water is maintained for a time in a state of vapour; but as the vapour cools, or, in other words, loses its motion, the water molecules coalesce to form a liquid. And now we are approaching a new and wonderful display of force. No one who had only seen water in its vaporous or liquid form could imagine the existence of the forces to which I am now about to refer; for, as long as the substance remains in a liquid or vaporous condition, the play of these forces is masked by the agitation kept up by the heat among the molecules. But let the heat be gradually withdrawn, the antagonist to their union being removed, the molecules begin to form new combinations. Like the particles of iron in our magnetic experiment, the water molecules are endowed with attractive and repulsive poles, and they arrange themselves together in accordance with these attractions and repulsions. Solid crystals of water are thus formed, to which we give the familiar name of ice. To the eye of science, these ice crystals are as precious as the diamond—as purely formed, as delicately built. Where no disturbing causes intervene, there is no disorder in this crystalline architecture. By their own structural power molecules build themselves on to molecules with a precision infinitely greater than that attainable by the hands of man. We are apt to overlook the wonderful when it becomes common. Imagine the bricks and stones of this town of Dundee endowed with locomotive power. Imagine them attracting and repelling each other, and arranging themselves in consequence of these attractions and repulsions so as to form streets and houses and Kinnaird Halls; would not that be wonderful? No less wonderful is the play of force by which the molecules of water build themselves into the sheets of crystal which roof your ponds and lakes every winter. To use the language of the American poet, Emerson, "the atoms march in tune," moving to the music of law, which thus renders the commonest substance in nature a miracle of beauty to the mental eye. It is the function of science, not as some think to divest this universe of its wonder and its mystery, but, as in the case here before us, to point out the wonder and the mystery of common things.

Over a plate of perfectly clean glass I pour a little water in which a crystal has been dissolved. A film of the solution clings to the glass; and now I wish to make this film crystallise before your eyes. By means of a microscope and electric lamp, I throw an image of the plate of glass upon the screen. The beam of the lamp, besides illuminating the glass, also heats it; evaporation is thereby promoted, and, at a certain moment, when the solution has become supersaturated, splendid branches of crystals shoot out over the screen. A dozen square feet of surface are now covered by those beautiful forms. Here we have crystalline spears shooting over the screen, feathered right and left by other spears. Molecule thus closes with molecule, until, finally, the whole subsides into crystalline rigidity. I move a new portion of the film into the beam. From distinct nuclei in the middle of the field of view the crystalline spears shoot with magical rapidity in all directions. For a moment the whole film appears to be alive, and now it has sunk into molecular repose. The film of water on a window pane on a frosty morning exhibits effects quite as wonderful as these. Latent in this formless solution, latent in every drop of water lies this marvellous structural power, which only requires the withdrawal of opposing forces to bring it into action. These experiments show that the common matter of our earth—"brute matter," as Dr. Young calls it—when its atoms and molecules are permitted to bring into free play the forces with which they are endowed, arranges itself under the operation of these forces, into forms which rival in beauty those of the vegetable world. And what is the vegetable world itself but the result of the complex play of these molecular forces. Here, as elsewhere throughout nature, if matter moves it is force that moves it; and if a certain structure is produced it is through the operation of the forces with which the atoms and molecules composing the structure are endowed. These atoms and molecules resemble little magnets with mutually attractive and mutually repellent poles. The attracting poles unite, the repellent poles retreat from each other, and vegetable forms are the final expression of this complicated play of molecular force. In the formation of our lead and silver trees, we needed an agent to wrest the lead and the silver from the acids with which they were combined. A similar agent is required in the vegetable world. The solid matter of which our lead and silver trees were formed was, in the first instance, disguised in a transparent liquid; the solid matter of which our woods and forests are composed is also, for the most part, disguised in a transparent gas, which is mixed in small quantities with the air of our atmosphere. That gas is formed by the union of carbon and oxygen, and is called carbonic acid gas. Two atoms of oxygen and one of carbon unite to form the molecule of carbonic acid which, as I have said, is the material from which wood and vegetable tissues are mainly derived. The carbonic acid of the air being subjected to an action somewhat analogous to that of the electric current in the case of our lead and silver trees, has its carbon liberated and deposited as woody fibre. The watery vapour of the air is subjected to a similar action; its hydrogen is liberated from its oxygen, and lies down side by side with the carbon in the tissues of the tree. The oxygen in both cases is permitted to wander away into the atmosphere. But what is it which thus tears the carbon and the hydrogen from the strong embrace of the oxygen? What is it in nature that plays the part of the electric current in our experiments? The rays of the sun. The leaves of plants absorb both the carbonic acid and the aqueous vapour of the air; these leaves answer to the cells in which our experiments on decomposition by the electric current took place. In the leaves the solar rays decompose both the carbonic acid and the water, permitting the oxygen in both cases to escape into the air, and allowing the carbon and the hydrogen to follow the bent of their own forces. And just as the molecular attractions of the silver and the lead found expression in the production of those beautiful branching forms seen in our experiments, so do the molecular attractions of the liberated carbon and hydrogen find expression in the architecture of grasses, plants, and trees.

In the fall of a cataract or the rush of the wind we have an example of mechanical power. In the combinations of chemistry and in the formation of crystals and vegetables we have examples of molecular power. Before proceeding further I should like to make clear to you the present condition of the surface of the globe with reference to power generally. You have learned how the atoms of oxygen and hydrogen rush together to form water. I have not thought it necessary to dwell upon the mighty mechanical energy of their act of combination, but, in passing, I would say that the clashing together of 1 lb. of hydrogen and 8 lbs. of oxygen to form 9 lbs. of aqueous vapour, is greater than the clash of a weight of 1,000 tons falling from a height of 20 feet against the earth. Now, in order that the atoms of oxygen and hydrogen should rise by their mutual attractions to the velocity corresponding to this enormous mechanical effect, a certain distance must exist between the particles. It is in rushing over this distance that the velocity is attained. This idea of distance between the attracting atoms is of the highest importance in our conception of the system of the world. For the world may be divided into two kinds of matter; or rather the matter of the world may be classified under two distinct heads—namely, of atoms and molecules which have already rushed together and thus satisfied their mutual attractions, and of atoms and molecules which have not yet rushed together, and whose mutual attractions are, therefore, as yet unsatisfied. Now, as regards motive power, the working of machinery, or the performance of mechanical work generally by means of the materials of the earth's crust, we are entirely dependent on those atoms and molecules whose attractions are as yet unsatisfied. Those attractions can produce motion, because sufficient distance intervenes between the attracting molecules, and it is this molecular motion that we utilise in our machines. Thus we can get power out of oxygen and hydrogen by the act of their union, but once they are combined, and once the motion consequent on their combination has been expended, no further power can be got out of the mutual attraction of oxygen and hydrogen. Their mutual attractions are then satisfied, and as dynamic agents they are dead.

Now, if we examine the materials of which the earth's crust is composed, we find them to consist for the most part of substances whose atoms have already closed in chemical union—whose mutual attractions are satisfied. Granite, for instance, is a widely diffused substance; but granite consists, in great part, of silicon, oxygen, potassium, calcium, and aluminium, the atoms of which substances met long ago in chemical combination, and are therefore dead. Limestone is also a widely-diffused substance. It is composed of carbon, oxygen, and a metal called calcium. But the atoms of those substances closed long ago in chemical union, and are therefore dead. And in this way we might go over the whole of the materials of the earth's crust, and satisfy ourselves that though they were sources of power in ages past, and long before any being appeared on the surface of the earth capable of turning their power to account, they are sources of power no longer. And here we might halt for a moment to remark on that tendency so prevalent in the world, to regard everything as made for human use Those who entertain this notion hold, I think, an overweening opinion of their own importance in the system of nature. Flowers bloomed before men saw them, and the quantity of power wasted before men could utilise it is all but infinite compared with what now remains to be applied. The healthy attitude of mind with reference to this subject is that of the poet, who, when asked whence came the rhododendron, replied—

> "Why wert thou there, O rival of the rose?
> I never thought to ask, I never knew,
> But in my simple ignorance supposed
> The self-same power that brought me there brought you."

A few exceptions to this general state of union of the particles of the earth's crust—all-important to us, but trivial in comparison to the total store of which they are but the residue—still remain. They constitute our main sources of motive power. By far the most important of these exceptions are our beds of coal, composed chiefly of carbon, which has not yet closed in chemical union with oxygen. Distance still intervenes between the atoms of carbon and those of oxygen, across which the atoms may be impelled by their mutual attractions; and we can do nothing more than utilise the motion produced by this attraction. Once the carbon and the oxygen have closed together, so as to form carbonic acid, their mutual attractions are satisfied; and while they continue in this condition, as dynamic agents they are dead. Our woods and forests are sources of mechanical energy, because they also have the power of uniting with the atmospheric oxygen, and the molecular motion produced in the act of union may be turned to mechanical account. And let it be remembered that the source of motive power here referred to is also the source of muscular power. A horse can perform work, and so can a man; but this work is at bottom the molecular work of the elements of the food and the oxygen of the air. We inhale this vital gas. We bring it into sufficiently close proximity with the carbon and the hydrogen of the food. They unite in obedience to their mutual attractions, and their motion towards each other, properly turned to account by the wonderful mechanism of the body, becomes muscular motion.

One fundamental thought pervades all these statements: there is one tap-root from which they all spring. This tap-root is the ancient maxim that out of nothing nothing comes; that neither in the organic world nor in the inorganic is power produced without the expenditure of other power; that neither in the plant nor in the animal is there a creation of force or motion. Trees grow, and so do men and horses; and here we have new power incessantly introduced upon the earth. But its source, as I have already stated, is the sun. For he it is who separates the carbon from the oxygen of the carbonic acid, and thus enables them to recombine. Whether they recombine in the furnace of the steam-engine or in the animal body, the origin of the power they produce is the same. In this sense we are all "souls of fire and children of the sun." But, as remarked by Helmholtz, we must be content to share our celestial pedigree with the meanest living thing. The frog, and the toad, and those terrible things, the monkey and the gorilla, draw their power from the same source as man.

Some estimable persons here present very possibly shrink from accepting these statements; they may be frightened by their apparent tendency towards what is called materialism—a word which to many minds expresses something very dreadful. But it ought to be known and avowed that the physical philosopher, as such, must be a pure materialist. His inquiries deal with matter and force, and with them alone. The action which he has to investigate is necessary action, not spontaneous action—the transformations, and not the creation, of matter and force. And whatever be the forms which matter and force may assume, whether in the organic world or the inorganic, whether in the coal beds and forests of the earth or in the brains and muscles of men, the physical philosopher will make good his claim to investigate them. It is perfectly vain to attempt to stop investigation as to the actual and possible combinations of matter and force. Depend upon it, if a chemist, by bringing the proper materials together, could produce a baby he would do it. And why not? There is no command forbidding him to do it—his inquiries in this direction are limited solely by his own capacity and the inexorable laws of matter and force. At the present moment there are, no doubt, persons experimenting on the possibilities of producing what we call life out of inorganic materials. Let them pursue their studies in peace; it is only by such trials that they will learn the limits of their powers.

But while I thus make the largest claim for freedom of investigation—while I as a man of science feel a natural pride in scientific achievement, while I regard science as the most powerful instrument of intellectual culture, as well as the most powerful ministrant to the material wants of men, if you ask me whether science has solved, or is likely to solve, the problem of this universe, I must shake my head in doubt. We have been talking of matter and force; but whence came matter, and whence came force? You remember the first Napoleon's question, when the *savans* who accompanied him to Egypt discussed in his presence the problem of the universe, and solved it to their apparent satisfaction. He looked aloft to the starry heavens, and said—"It is all very well, gentlemen, but who made all these?" That question still remains unanswered, and science makes no attempt to answer it. As far as I can see, there is no quality in the human intellect which is fit to be applied to the solution of the problem. It entirely transcends us.

The mind of man may be compared to a musical instrument with a certain range of notes, beyond which in both directions we have an infinitude of silence. The phenomena of matter and force lie within our intellectual range, and as far as they reach we will at all hazards push our enquiries. But behind, and above, and around all, the real mystery of this universe remains unsolved; and here the true philosopher will bow his head in humility, and admit that all he can do in this direction is no more than what is within the compass of an ordinary child. Fashion this mystery as you will, with that I have nothing to do. But be careful that your conception of the Builder of this universe is not an unworthy conception. Invest that conception with your grandest, and highest, and holiest thought, but be careful of pretending to know more about it than is given to man to know. Be careful, above all things, of professing to see in the phenomena of the material world the evidences of Divine pleasure or displeasure. Doubt this all ye who would deduce from the fall of the Tower of Siloam, the sin and wickedness of those who were crushed by the fall! Doubt this all ye who pretend to see in cholera, cattle plague, and bad harvests, the evidence of Divine anger! Doubt this—but it requires some courage to say these things in Scotland—all ye who assert that the depreciation of railway scrip is a consequence of railway travelling on Sundays. You know nothing about it. To such I say in substance, what was said by one of the mightiest Scotchmen living or dead—Thomas Carlyle—to the followers of Dr. Pusey—

> "The Builder of this universe was wise,
> He formed all souls, all systems, planets, particles;
> The plan he formed his worlds and Æons by,
> Was—Heavens!—was thy small nine-and-thirty articles!"

I now resume my report of the proceedings.

SECTION B. CHEMICAL SCIENCE.

Friday, September 6th.

The following papers were read:—

"*On the present use of Lichens as Dye Stuffs*," by Lauder Lindsay.

In the absence of the author this paper was read by Dr. Odling. He said—It had been expected that the aniline dyes—a product from the distillation of coal tar—discovered a few years ago, would supersede the lichenous dye stuffs previously in use, and that the latter would speedily disappear, in consequence of the breaking up of the Highlands by railways—and the improvement of the communication between Glasgow, Edinburgh, and the south. To him, however, it seemed that all such predictions were at least premature. He confessed that such was the eminence and experience of the authorities, that for a time he acquiesced in their conclusions, and took it for granted that they were well grounded; but in the course of his investigations for a work which he had in preparation on lichenology, he had found that there existed abundant evidence of the use of lichens in commercial manufactures on a large scale, as well as for domestic purposes. Dr. Lindsay then stated that from facts which he had learned at the Exhibition of 1862, from his investigations while on a tour through the Orkney and Shetland Islands, and parts of the Highlands, and from numerous writers whom he quoted, he had come to conclusions favouring the belief that lichens would not be superseded, at least for a long time to come. He then proceeded to give numerous details of the use of lichen dyes for commercial and domestic purposes, to remark on the unsatisfactory state of the nomenclature and classification of the lichens, and to advocate a uniform system.

"*A Note on Messrs. Wanklyn, Chapman, and Smith's Method of Determining Nitrogenous Organic Matters in Water*," by Dugald Campbell, F.C.S.

At the last meeting of the Chemical Society, June 20th, Professor J. A. Wanklyn read an extract from a paper by himself, Mr. E. T. Chapman, and Mr. M. H. Smith, "*On Water Analysis, and the Determination of Organic Matter in Water*," in which they proposed a mode of estimating the amount of nitrogenous matter contained in water, whether it exists as ammonia, or urea, or as albuminous matter; a report of this is given in the Chemical News of July 5, p. 7. (*Am. Reprint, Sept.* 1867, *p.* 134.)

Having for a number of years worked specially on the estimation of nitrogen in solutions containing ammonia, urea, and albuminous matters, I was much struck with the results which were given by these gentlemen, and at the time when the paper was read I expressed my doubts as to the accuracy of their observations, my own having been so diametrically opposite; still, although nothing was said on the reading of the extract about the actions being different with *moderately strong* and *very dilute* solutions, yet after my remarks something was said by one of the gentlemen (Mr. Chapman) in the discussion about strong solutions requiring different treatment; and remembering that my experiments had all been made upon what might be termed moderately strong solutions, certainly not very dilute solutions, I was silent, as I thought this might possibly account, at least to some extent, for the great differences in our results; still I did not think this could wholly account for them.

Since then, however, I have made a number of experiments with very dilute solutions of both urea and albumen, the results of which in a great measure, if not entirely, confirm my views stated at the time, viz. that urea is not perfectly decomposed by distilling with sodic carbonate as described by these gentlemen, and likewise that I had invariably detected ammonia in the distillate from a solution of albuminous matter when it was distilled under similar circumstances.

As regards the first part of the process, which is the estimation of ammonia in the water, and which is in my opinion a very material one, but which appears to me to have been passed over by these gentlemen as a thing of very little importance, all we are told of it is that "when the quantity of ammonia present in the original water is large it is determined directly, unless the water is too much coloured." In all the experience which I have had in determining the amount of ammonia in water, by Nessler's test, working on the usual scale, I have never been able to apply it with any degree of accuracy to the original water, but always had to distil the water with some alkali and test the distillate; and this I know is the general experience; and if urea is so readily broken up in the distillation of water, as it is said to be by these gentlemen, I should have thought that some means of distilling the water in order to obtain from it the ammonia, without decomposing the urea, should have been given, and that a process for estimating the ammonia, urea, and albuminous matters in water would scarcely be complete without it.

After the determination of the ammonia, the next operation, we are told, is to introduce a litre of the water "into a retort with two grammes of sodic carbonate, and rapidly distil, the distillate being collected in a flask containing 100 c.c. When this is filled the receiver is changed, and another 100 c.c. distilled off; this is repeated a third time, and it is now found that all the nitrogen present in the original water, in the form of urea, has passed over in the form of ammonia. The ammonia in the distillate is then determined by Nessler's test."

I may state that in Parliament, and generally throughout the kingdom, when reports are made upon the analysis of waters, the results are required to be given in grains, or parts of a grain, in a gallon of the water of 70,000 grains at 60° Fahrenheit, and they are thus much more readily understood by engineers and the public generally, who are interested in these matters, than when otherwise expressed. I have, therefore, in the following experiments thought it best to state that the waters operated upon contained so many parts of a grain of the substance being experimented upon per gallon, and also to use grains in making the solutions in other parts of the experiments; but I have retained the litre and cubic centimeter measures, as I wished to follow explicitly the experiment as it is given above, as to the quantity of water taken for distillation and the amount of each of the distillates, in case anything might be said of my not having done so.

The first experiments were made with a solution of urea equal to the $\frac{1}{20}$th part of a grain of urea in a gallon of water, Prof. Wanklyn having given this as a quantity by which his process could be tried, and with which he said it would work satisfactorily, as it had been described in their paper. The following are the details and results:—

A litre of water was taken in which was dissolved an amount equal to 0·011 grain of urea containing the elements of 0·0062 grain of ammonia, and introduced into a retort capable of holding twice this quantity. 30·87 grains (two grammes) of sodic carbonate were then added, and the distillation was proceeded with rapidly, and the distillate collected exactly as described above. The ammonia which was found only in the two first 100 c.c., and estimated by Nessler's test, gave 0·0026 grains, or about one-third of the ammonia present in the urea taken.

There being no trace of ammonia in the third 100 c.c., I should from the statements of Messrs. Wanklyn, Chapman, and Smith, have concluded that all the urea was decomposed into ammonia, had I not known the quantity of urea which was taken at the outset, and also from my former experiments upon stronger solutions of urea which acted very similarly; but knowing this, a solution of potassic hydrate was introduced into the retort, and the distillation proceeded with exactly as before described; the two first 100 c.c., which were distilled over, contained 0·002 grains of ammonia, and the third distillate containing no ammonia; potassic permanganate was added in crystals to the liquid in the retort until it was deeply coloured, and the distillation was again proceeded with as above; the remainder of the ammonia, which was estimated at 0·0015 grain, was in the first and second, but principally in the first 100 c.c., and none in the third. Altogether the ammonia obtained was 0·0061 grain, the calculated quantity being 0·0062 grain.

This experiment was repeated as above described, but with somewhat different results, the distillations with the sodic carbonate giving 0·0021 grain, the potassic hydrate 0·0016 grain, and the potassic permanganate 0.0025 grain, altogether 0·0062 grain of ammonia, which is exactly the quantitity of ammonia in the urea taken.

Experiments were next made with a solution of urea equal to $\frac{1}{40}$th part of a grain of urea in a gallon of water, and the following are the details and results:—

A litre of water was taken in which was dissolved a quantitity equal to 0·0055 grain of urea, containing the elements of 0·0031 grain of ammonia, and distilled as above with sodic carbonate; in the first two 100 c.c., the ammonia present amounted to 0·001 grain; in the third 100 c.c., there was no ammonia; potassic hydrate gave in the first two 100 c.c. 0·001 grain of ammonia, in the third none, and potassic permanganate gave in the first two 100 c.c., but principally in the first, 0·0011 grain of ammonia, making altogether 0·0031 grain of ammonia, which is the exact quantity of ammonia in the urea taken.

This experiment was repeated exactly as above, but as in the former case, with slightly different results; sodic carbonate gave 0·001 grain, potassic hydrate gave 0·0001 grain, and potassic permanganate 0·002 grain ammonia, making altogether 0·0031 grain of ammonia.

Experiments were next made with a solution of urea equal to $\frac{1}{80}$th part of a grain of urea in a gallon of water, and the following are the details and results:—

A litre of water was taken, in which was dissolved an amount equal to 0·0025 grain of urea, containing 0·00155 grain of ammonia, and treated in the same manner as in the preceding experiments; with sodic carbonate it gave 0·0013 grain ammonia in the first two 100 c.c., and no ammonia in the third; with potassic hydrate 0·0001 grain in the first two 100 c.c., and none in the third; and with potassic permanganate, gave 0·0001 grain of ammonnia; altogether within a fraction of the amount of ammonia in the urea employed.

This experiment was repeated, and the results were as follows:—With sodic carbonate, 0·0008 grain, with potassic hydrate 0·0003 grain, and with potassic permanganate 0·0004 grain; altogether 0·0015 grain of ammonia, and making the same amount of ammonia as the last, but evolved differently.

Experiments were next made with a solution of urea equal to the 100th part of a grain of urea in a gallon of water, and the following are the details and results:—

A litre of water was taken in which were dissolved 0·0022 grain of urea containing 0·00136 grain of ammonia, and distilled as above; with sodic carbonate in the first two 100 c.c. there were 0·001 grain of ammonia, and no ammonia in the third 100 c.c.; and by potassic hydrate in the first two 100 c.c. 0·0003 grain; whilst by potassic permanganate there was no ammonia. The ammonia distilled off was altogether 0.0013 grain, which is a fraction less ammonia than was contained in the urea employed.

This experiment was repeated with a nearly similar result.

Experiments were next made with a solution of urea equal to the $\frac{1}{120}$th part of a grain of urea in a gallon of water, and likewise with still smaller portions of urea, when it was found in all cases that with sodic carbonate all the ammonia contained in the urea distilled over in the first 100 c.c.

From these experiments it would appear that urea is decomposed entirely when distilled in the ordinary manner with sodic carbonate, but only when in extremely dilute solutions; requiring the assistance of potassic permanganate to decompose it even when so dilute as in the proportion of the $\frac{1}{80}$th part of a grain of urea in a gallon of water, or one part in five millions; and requiring the assistance of potassic hydrate to decompose it even when diluted to an extent above one part in seven millions; and that is only decomposed by sodic carbonate alone when diluted somewhat above this point.

I may add that these and all other experiments were made with distilled water, which tried in every way showed not a trace of ammonia by Nessler's test, and that every experiment was made by dissolving at the time fresh crystals of urea; or, in other words, that no solution of urea was employed which had been made or kept any time. I may also add that I found a considerable difference in the various specimens of urea which I examined; all gave distinct indications of ammonia by the Nessler test; the larger, less coloured, and finer the crystals the more was the ammonia. I need scarcely add that working upon such very dilute solutions as I was doing, the latter specimens yielded sensibly more ammonia by the sodic carbonate and potassic hydrate than those showing less indications of ammonia by the Nessler test; still I do not doubt that working with any ordinary urea, the results will not be far different from my own, although variable.

The next part of the process to which I wish to call attention is the estimation of what is termed the "albuminous substances."

According to Messrs. Wanklyn, Chapman, and Smith, albumen, such as from white of egg, yields no ammonia, ascertained by Nessler's test, when a solution of albumen is distilled with the proportions of sodic carbonate, 30·87 grains (2 grammes), which they say they use to decompose the urea; whereas, as I stated before, in all my experiments I had invariably found that ammonia was evolved under such circumstances. I may observe that hitherto my experiments had been made upon what might be termed rather strong solutions (one grain of dry albumen in a gallon of water), and hence I was led to make the following experiments with what I conceive to be weak solutions:—

The first experiment was made with a quantity about equal to the $\frac{1}{20}$th part of a grain of dry albumen to 1 gallon of water.

100 grains of the white of new-laid eggs, dried, gave 12·00 grains of dry residue containing 1·884 grains of ammonia; or 100 grains of such white of egg contained 1·884 grains of ammonia.

A litre of water was taken in which was dissolved an amount equal to 0·093 grain of white of egg containing 0·00175 grain of ammonia, and was distilled with 30·87 grains (2 grammes) of sodic carbonate; in the two first 100 c.c. of the distillate 0·0006 grain of ammonia were estimated by Nessler's test, in the third 100 c.c. there was not a trace of ammonia; potassic hydrate was then added, and the distillation was gone on with as before, when not a trace of ammonia was discovered in any of the three 100 c.c. distilled; potassic permanganate was then added, and the distillation proceeded with, when it gave, principally in the first distillate, 0·001 grain of ammonia. Altogether there was a loss of 0·00015 grain of ammonia in the albumen.

This experiment was repeated with somewhat similar results, only rather more ammonia was evolved by the sodic carbonate, and again none by the potassic hydrate, and the remainder by the potassic permanganate.

The next experiment was made with about $\frac{1}{40}$th part of a grain of dry albumen to a gallon of water, as follows:—

A litre of water was taken, in which was dissolved an amount equal to 0·0466 grain of white egg, containing 0·00087 grain of ammonia, and distilled with the sodic carbonate. The two first contained 0·0007 grain of the ammonia; potassic hydrate gave no ammonia in any of the three 100 c.c., and potassic permanganate gave 0·0001, which is a loss of 0·00007 of a grain of the ammonia contained in the white of egg employed.

Another experiment was made with a quantity equal to the $\frac{1}{80}$th part of a grain of dry albumen to a gallon of water, as follows:—

A litre of water was taken in which was dissolved an amount equal to 0.0233 grain of white of egg, containing 0·000435 grain of ammonia, and distilled with the sodic carbonate, the first two 100 c.c. gave 0·0002 grain of ammonia. By the potassic hydrate no ammonia was given off, and by the potassic permanganate 0·0002 grain, showing altogether a loss of ammonia equal to 0·000035 grain.

Another experiment was made with a quantity about equal to the $\frac{1}{160}$th part of a grain of dry albumen to a gallon of water, as follows:—

A litre of water was taken in which was dissolved 0·01165 grain of white of egg, containing 0·000217 grain of ammonia, and distilled with the sodic carbonate. In the first two 100 c.c. of the distillate all the ammonia was evolved, in the third 100 c.c. there was none, nor when distilled with potassic hydrate or potassic permanganate was there a trace to be found.

This experiment was repeated and with the same results, all the ammonia being evolved in the first two 100 c.c. when the solution was distilled with sodic carbonate alone.

In all these experiments it will be seen that with the sodic carbonate a distinct quantity of ammonia is evolved, and likewise that in all these experiments, strange though it may appear, after the ammonia has been evolved as far as is possible by the sodic carbonate, that potassic hydrate evolves not even a trace, and it is only on the addition of potassic permanganate that the final quantity of nitrogen is expelled as ammonia. It will likewise be seen that, as in very dilute solutions of urea, all the nitrogen is expelled as ammonia by the sodic carbonate, so likewise this is the case in very dilute solutions of albumen.

The whole of the above experiments, both with the urea and the albumen, were conducted in ordinary retorts of not less than twice the capacity of the liquid to be distilled, and as nearly all alike in shape and size as it was possible to get them, and every endeavour was made to distil the solutions at a rapid speed and as nearly under the same circumstances as possible, otherwise I do not think the results obtained would have been so regular as they are, but as far as I can judge from other experiments quite the reverse; still on the whole they would be generally confirmatory of the results I have obtained.

Since making these experiments, my attention has been directed to a paper by Mr. Chapman, "on Nessler's test for Ammonia," wherein that gentleman says that in comparing a solution to be tested with the ammonia standard, after adding the test he allows the liquids to stand for ten minutes before he compares them. My own experience, and I know it is that of others, is that this time is not nearly sufficient to develope the colour properly, and this is especially the case with very dilute solutions of ammonia; that being so I do not see why such solutions should not be allowed to stand until the colour is fully developed in them, although it may take a longer time. in which case experience has taught us that the results are a deeper and more defined colour, which admits of better, I might almost say, of perfect comparison. In carrying out the above experiments sufficient time was invariably allowed for the proper development of the colour when determining the amount of ammonia in all of the distillates.

"*A Description of a New Ether Anemometer.*"

By ALFRED E. FLETCHER,

GOVERNMENT INSPECTOR OF ALKALI WORKS FOR THE WESTERN DISTRICT.

The construction of this apparatus is based on the fact that a current of air passing across the open end of a straight tube causes a partial vacuum in it.

An application of this principle is seen in a small toy in common use, in which a liquid is made to ascend several inches in a vertical tube by blowing through another tube across its open end. It rises by virtue of the partial vacuum caused by the current of air which crosses it.

If then a straight tube is inserted through a hole in the brickwork of a chimney or flue, so that the current of air in the flue passes across its open end, a partial vacuum will be formed in it, greater or less in proportion to the velocity of the current.

A tube in such a position will, however, communicate a suction arising from that of the chimney itself, besides that suction produced by the current of air passing across its open end, and for the present purpose these two must be distinguished.

To effect this *two* tubes should be inserted in the chimney, one of them having a straight and the other a bent end, the bend to be turned so as to meet the current of air; both tubes are open. In each of these tubes will be experienced the partial vacuum due to the suction of the chimney itself. In the straight tube, however, this will be increased by the suction caused by the passage of the current of air across its open end, while in the case of the bent tube this will be diminished by the pressure caused by the current of air blowing into it. The difference therefore between the suction in the two tubes will be due to the action of the current of air in the chimney, and it remains only to measure this difference in order to measure the velocity of the current itself.

To effect this let these tubes be connected with a U tube containing water, one with each limb; then the water will be raised up in one limb to a degree corresponding with the difference of suction, so that the difference of level of the water in the U tube, being a measure of the difference of suction in the tubes, becomes a measure of the velocity of the current of air in the chimney. By this arrangement the suction power of the chimney itself is eliminated, for it operates equally on each limb of the U tube, while the difference of pressure experienced will be due only to the different action of the current of air in the flue on the tube with the straight end and the one with the bent end.

It remains, then, to register accurately this difference of level of the water in the U tube, and to construct a formula connecting it with the speed of the current of air in the flue, so that by measuring the one the other may be measured also.

Experiment showed that for high speeds of air the measurement of the difference of this water level was easy, but that or speeds below 5 feet per second the amount became too minute and uncertain for practical use.

Many plans were then devised for constructing a pressure gauge which should be more delicate than the ordinary U tube.

Efforts were first made to modify the U tube so that its range might be increased and its indications magnified. This might be done by drawing out its lower bend horizontally and increasing the size of the vertical portions till it assumed the form of two vertical cylinders connected by a long horizontal tube. If now a pressure were exerted which would cause a depression of the water in one limb, the motion so caused in the narrow column of water in the horizontal tube would be so much greater, as its sectional area was smaller than that of the vertical tubes. It was found, however, that in proportion as a greater range in the scale of the instrument was thus obtained, a greater amount of friction must also be encountered, and that thus the advantage of the one was neutralised by the evil of the other.

It is necessary to see this clearly in order to arrive at the conclusion that *all* methods of increasing the actual motion of the fluids or of magnifying it by any mechanical arrangement of levers or otherwise, must be open to the same objection. This proposition seems clear now, in the light shed by a long series of failures encountered in the attempt to act contrary to it, but it was not clear before.

The simple U tube was therefore returned to, and means adopted for accurately seeing and measuring its slightest indications. In the first place, the limbs were increased until they were no longer small tubes of about 0·4 inch internal diameter, but cylinders of 4 inches diameter; these were connected at the bottom by a small tube. Thus the power exerted by the pressure communicated through the connecting tubes, operating on the extended surface of the liquid in the cylinders, was increased a hundred-fold over that operating in the smaller U tube; but the friction could only have been increased tenfold, giving therefore a tenfold increase of delicacy. In order to observe accurately the rise and fall of the liquid in the cylinders floats were introduced, on each of which was engraved a very fine horizontal line; and to measure accurately the comparative elevation or depression of these two lines, a finely divided scale and vernier were added, working with a delicate screw adjustment. With this it is possible to measure an elevation or depression of $\frac{1}{1000}$ inch, which is sufficiently accurate for the purpose in view.

On trying now to apply the instrument so constructed, and attempting to measure very minute variations of pressure, failure still seemed imminent; for although the motion of the water in the increased limbs of the U tube could be measured to $\frac{1}{1000}$ inch, the water refused to move, except under pressures exceeding that which would be indicated by so small a column; in other words, the water seemed to stick in the cylinders. It was necessary, therefore, to make experiments with various liquids in order to choose one more suitable than water; for this purpose a very thin plate of metal was suspended from the beam of a delicate balance, and the amount of power required for its immersion in, and subsequent withdrawal from, various liquids thus measured. This resistance is due to what is often called capillary attraction and repulsion; it is shown to exist largely in water, by the fact that a needle may be made to rest on its surface without sinking. In the case of water 20 grains were needed to overcome it, while with many other liquids a much less force sufficed, and in the case of ether $\frac{1}{100}$ grain was sufficient. Ether was, therefore, chosen as the liquid which offered the least resistance, and also on account of its low specific gravity.

After substituting ether for water, the action of the manometer was quite satisfactory, the lines on the floats always return exactly to their original position after any disturbance, and its indications could be relied on to $\frac{1}{1000}$ inch.

It remained now to ascertain the value of these indications when applied to the measurement of the velocity of air.

Calculation might lead to this, but it was thought much better to depend, if possible, on actual experiment, and by testing the instrument with currents of air of known velocity to draw up a table for future use.

The following plan was adopted and found perfectly successful:—

A flue 14 inches diameter, 100 feet long, was constructed of iron pipes, one end was connected with the base of a high chimney, the other left open. A sliding plate of metal, capable of cutting off the connection between the chimney and the flue, served to regulate at will the amount of air drawn through it. At the open end of the flue a red-hot brick was placed, and on it was thrown at stated times a few drops of sulphuric acid. This raised instantly a dense cloud of white vapour, which, passing along the flue, could be observed to reach the other end, by looking through two holes bored through opposite sides of it. It remained now only to note the time occupied by the passage of the cloud of vapour along the flue to know the speed at which the air was passing through it. At the same time the tubes in connection with the ether manometer were in the flue and under the influence of the same current of air, so that the simultaneous reading of the instrument could be taken. By now altering the position of the slide which regulated the admission of air to the flue, the speed from time to time was altered, and a corresponding observation by the manometer obtained.

By the aid of this ether manometer the speed of any current of air in flues or chimneys can be measured by simply boring a hole one inch diameter through the brickwork and inserting two tubes, one with a bent, the other with a plain straight end as already described, and making the necessary observation of the floats; and in this operation neither soot, heat, nor corrosive vapours can prove any hindrance.

So sensitive is the apparatus that on a windy day the effect of each successive gust of wind is observable, as it causes variations in the draught of the chimney.

The instrument may be used as a wind gauge by fixing through the roof of an observatory a small vertical pipe, presenting a plain open end to the wind. The lower end of this pipe brought down into the observatory and connected with the ether manometer would communicate the varying pressures due to the varying speed of the wind.

"*On an Apparatus for Indicating the Presence and Amount of Fire-damp in Mines,*" by George F. Ansell.
